Abstract: Sixty-four specimens collected passively from patients with cutaneous ulcers suggestive of leishmaniasis attending hospital and health centres in all parts of Iraq for diagnosis were included in the study. The present study was conducted from June to December 2012 in Al-Karamah Teaching Hospital in Wasit Province, Iraq. Dermal scrapings were analysed both by parasitological (examination of Giemsa-stained smears and in vitro cultivation) methods and by a genus-specific PCR detection. Microscopy revealed amastigotes in 38 samples (59.4%) and in vitro cultivation gave positive results in 19 cases (29.7%), whereas PCR detected Leishmania in 44 samples (68.75%). There are two forms of Cutaneous leishmaniasis (CL) in Iraq are caused by two species of Leishmania. Of 44 well-documented cases in our study; 28 (63.6%) were caused by Leishmania major and 16 (36.4%) by Leishmania tropica.

Keywords: Cutaneous Leishmaniasis, PCR, Diagnosis

1. Introduction

Molecular epidemiology is a fairly new branch of science that has emerged in the last 20 years in parallel with the development of molecular biology (1). Leishmaniae are sand fly-borne parasites that appear as intracellular amastigotes within the macrophage phagosomes of the mammalian host, and as extracellular flagellated promastigotes in the gut of the sand fly or in vitro culture. Many species of sand flies are vectors of leishmaniasis. The most common are the Phlebotomus species in the eastern hemisphere, or Old World, and the Lutzomyia species in the western hemisphere, or New World. Generally, leishmaniasis is a zoonosis with humans acting as incidental hosts and other mammals (especially rodents and dogs) acting as reservoir hosts. There are, however, exceptions to this rule: Both Leishmania tropica and Leishmania donovani infection can be transmitted anthroponetically (2).

Generally, leishmaniasis is divided into three clinical syndromes: cutaneous, mucosal, and visceral infection. Cutaneous leishmaniasis is localized to skin. Mucosal leishmaniasis occurs mainly as a late complication in new-world CL and is associated particularly with infection by Leishmania (Viannia) species. Visceral leishmaniasis is caused predominately by L. donovani and Leishmania infantum-chagasi, though in the Arabian Gulf War, L. tropica caused a mild form of visceral disease referred to as viscerotropic leishmaniasis (3).

Cutaneous leishmaniasis (CL) caused by L. tropica and L. major are indistinguishable on clinical bases as both erupt in the same way, the size of the lesion ranging from a few millimeters to 4 centimeter or more. The site and number of lesions(s) are an indication of the type of CL. Leishmania major usually presents as multiple lesions (≥3) and L. tropica is more often on the nose (4,5). Cutaneous leishmaniasis is widespread throughout the country, except for the three provinces in the northeast, bordering Turkey and Iran, where cases are rare. It seems that the majority of CL cases reported in Iraq are caused by L.major (ZCL) (6). Two epidemic outbreaks of CL have been reported in Dinawia Province in 2008 with about 300 cases and in Baghdad/Rahmania in 2009 with about 400 cases. These may have been caused by CL by L. tropica (ACL), a very old disease in Iraq, also called "Baghdad boil", which used to be com-
mon until a few decades ago (7).

Cutaneous leishmaniasis occurs either as a zoonotic or as an anthropotonic infection. The transmission of Leishmania major causing Old World cutaneous leishmaniasis in humans is a rural zoonotic disease with rodents serving as the reservoir. In zoonotic leishmaniasis, humans are only accidental hosts and usually not directly involved in the transmission cycle. New endemic foci of CL may occur, when environmental changes take place such as rise of population under poor housing conditions (slums) or specific forms of agriculture (8).

The main insect vector for transmission of L. major is the sand fly species Phlebotomus papatasi (9). In some urban centers of Middle East and Asia exist completely anthropotonic life cycles of the parasites, i.e. human beings are the main or only reservoir host. In such places cutaneous leishmaniasis caused by L. tropica can be highly endemic, but no animal reservoir is to be recognized. In Central and South Western Morocco, the transmission of L. tropica is anthroponotically as well. The parasite is mainly transmitted by sandflies of the species Phlebotomus sergenti (10).

Diagnosis of leishmaniasis is based on clinical, parasitological, serological and molecular identification. Cutaneous leishmaniasis appear as papule or ulcer with crust center and raised edges (11). The serological tests based on the presence of antibody in the blood in visceral leishmaniasis (VL) and cell mediated immunity in cutaneous and mucocutaneous leishmaniasis (12) such as Leishmania skin test (Montenegro reaction), Indirect Fluorescent Antibody Test (IFAT), Direct Agglutination Test (DAT), and Enzyme Linked Immunosorbant assay (ELISA). The molecular tests are based on detection of nucleic acid such as Polymerase Chain Reaction (PCR) (13). The aims of this study to evaluate the reappraisal of the diagnosis and epidemiology of CL in some parts of Iraq, by different parasitological, cultural, and molecular assay.

2. Materials and Methods

2.1. Clinical Sample Collection

Clinical samples consisted of all confirmed cases that visited to hospital and private clinics in some parts of Iraq from June 2012 till December 2012 with the symptoms of Cutaneous leishmaniasis and presence of amastigotes in Giemsa-stained smears. The demographic features including patient’s sex, age, clinical signs including number of scars and its location in the body, month of diseases occurrence, incidence rate, and geographical regions were recorded.

Skin biopsies of 5 to 10 mm in diameter were taken under sterile conditions from the border of the ulcer and divided into three parts. The first part of the sample was smeared onto a glass slide, fixed with methanol, stained with Giemsa and examined by microscopy. A second part was inoculated on Novy-MacNeal-Nicolle (NNN) medium (14). The cultures were incubated at 24 °C and observed every week for 1 month. The third part for PCR was placed directly in lysis buffer (10 mM Tris-HCl, 10 mM EDTA).

2.2. Microscopical Examination

Small quantities of tissue obtained by skin scrapings were smeared on glass slides, air dried and fixed with methanol for a few seconds. Giemsa stain was filtered and diluted 1:20 with phosphate buffer (pH 7.2). After 20 minutes of staining the slides were washed with tap water and air dried. The stained smears were examined under the microscope with a 40 x lens and with a 100 x oil immersion lens. If at least one intra- or extra-cellular amastigote with a distinctive kinetoplast was found the smear was declared positive. When no amastigotes were seen after 15 minutes of inspection, the smear was declared negative. Many of the patient smears were double checked, the observations were in concordance.

2.3. Culture

The lesions and the adjacent normal-looking skin around them were cleaned, sterilized with 70% ethanol, and allowed to dry. Similar to the preparation of the slide smears, a small amount of the scraped tissue was inoculated on the liquid phase of Novy-McNeal-Nicolle (NNN) medium (10% of rabbit blood). The cultures were incubated at 25°C and examined for parasite growth by the inverted microscope and also light microscope every 4 days until promastigotes were seen or up to one month before being discarded as negative. The cultures were made at least in duplicates for each case (15).

2.4. DNA Extraction

Each fresh or dried smear was scraped off the slide with a sterile scalpel and the scrapings were added to 200 µl lysis buffer [50 mM Tris- HCl (pH 7.6), 1 mM EDTA, 1% (v/v) Tween 20] containing 8.5 µl of a proteinase K solution (19 µg/ml, in a 1.5 ml tube (11). The tube was incubated for 2 h at 56 °C before 200 µl of a phenol: chloroform :isoamyl-alcohol mixture (25:24:1, by volume) was added. After being shaken vigorously, the tube was centrifuged at 6000g for 10 min and then the DNA in the supernatant solution was precipitated with 400 µl cold absolute ethanol, resuspended in 50 µl double distilled water and then stored at -20 °C ,until it could be tested for leishmania kDNA (16).

2.5. PCR

PCR assay was performed according to the manufacturer’s protocol (Sinagen, Iran) with the final volume of 25 µL of each PCR reaction. PCR amplification was carried out in a DNA Thermal Cycler ( Master cycler gradient, San Leonardo, Canada) based on the following conditions: initial denaturation (95°C, 3 min; 63°C, 30 s; 72°C, 60 s) 1 cycle followed by 35 cycles including denaturation (93°C, 20 s), annealing (63°C, 20 s) and extension (72°C, 40 s). Finally, 10 µl of amplified samples without adding loading buffer.
were loaded in a 2% agarose gel containing 0.5 mg/mL ethidium bromide in electrophoresis and the products were visualized by Ultraviolet (UV) transillumination.

2.6. Statistical Analysis

The suitable statistical methods were used in order to analyze and assess the results. These were used to accept or reject the statistical hypotheses. All the statistical analysis were done by using Pentium-4 computer through the Minitab program and Excel application.

3. Results

Table 1. show the prevalence of positive cases of CL by using different diagnostic methods. The highest infection (68.75%) appeared by using PCR while the lowest infection (29.7%) appeared by culture on NNN media.

The comparison of the clinical features of CL cases was shown in table 3. Our study appeared that median duration of lesions was under 2 month (64.3%) in L.major cases and (68.75%) in L.tropica. Results of this study showed that most ulcers (64.3%) were in face and thirteen patients (46.4%) presented with single lesion.

4. Discussion

A round shape Leishmania parasite without flagellum was grown in culture media with biphasic NNN medium as demonstrated by light microscopy examination. The change of promastigotes to amastigotes did take place completely in culture with NNN medium. These finding again emphas-
ize that optimal condition for propagation of axenic amastigotes vary and have to be determined for each Leishmania species isolates. DNA isolated from promastigote forms obtained from in vitro culture of Leishmania allowed for optimization of PCR reaction (18).

The diagnosis of CL classically relies on microscopic examination and in vitro cultivation. These classical methods require the presence of a relatively high number of viable or morphologically intact parasites; this may pose a problem particularly in the chronic phase of CL where parasite levels in skin lesions are very low. In contrast, the molecular approach is both sensitive and specific (19). In this study we set up a well documented, genus-specific PCR to detect Leishmania species in clinical cutaneous samples and compared this method with classical methods. The PCR-based checking of Giemsa-stained smears appears to be reasonably sensitive and specific in revealing the presence of Leishmania parasites in such chronic lesions. PCR can clearly help improve the diagnosis of CL in these difficult cases.

Sixty-four patients with 81 skin lesions were enrolled in our study: 24 males (54.5%) and 20 females (45.5%). The highest infection (68.75%) appeared by using PCR while in our study: 24 males (54.5%) and 20 females (45.5%). The reason is that more men have been reported more frequently in men (54.5%) in comparison to women (45.5%). The reason is that more men work or sleep in open areas and is also due to men’s less covering than women and more exposure to the infected sand flies (27). Some studies have hypothesized that the gender difference observed in some parasitic disease can be attributed to hormonal effects. However, controversy still exists regarding the role of sex hormones in the cellular immune response (28,29). Although it is believed that sex hormones may influence the establishment and the course of parasitic diseases, behavioral factors, making male individuals more likely to be exposed to vectors in fields and other transmission environments, are probably equally or more important (30, 31). On the contrary of other studies that found the higher incidence of infection among females than males (32-34).

The majority of the CL cases (72.8%) in age groups under 12 years old, which may be due to several factors, such as children’s outdoor activities and sleeping outdoors, which increases exposure to sand fly bites during their active hours. The same result has been reported by some other researchers (25,32-35).

5. Conclusions

Characterization of Leishmania isolates collected from different parts of Iraq showed that L. major and L. tropica are the agents of CL. Moreover, this study revealed that PCR is a reliable method for diagnosis and identification of Leishmania species and can applied in epidemiologic investigations in Iraq.
