Abstract: Possibilities for adaptation to high altitude conditions by the method of controlled breathing are investigated. It is determined that voluntary reduction in respiratory rate (to 6 per minute) among school students living in highlands improves the heart functioning. It identifies the possibility to correct the disturbances revealed during the investigation through the method of controlled breathing.

Keywords: Adaptation to High Altitude, Respiratory Rate, Cardiovascular System, Controlled Breathing

1. Introduction

In recent years, there has been an increasing population living at high altitude (HA) due to immigration, work duty or tourism. With an increasing population living at a high altitude, the impact of high altitude residence on human cardiovascular functions has raised concerns [1].

Normal activity of the respiratory system ensures the biochemical and physiological processes in the body. The respiration cycle is an intermittent process repeated during whole life. Its role is not limited to oxygen inspiration and assimilation, and carbon dioxide expiration. Respiration also regulates the rate of oxidative reactions, the work of cardiovascular system, the course of energetic metabolism, the synthesis of ATP etc.

The overall purpose of the respiratory system is to provide oxygen for metabolism and eliminate the carbon dioxide produced. In the steady equilibrium state oxygen intake into the lungs is matched to oxygen consumption by the tissues, and carbon dioxide elimination in the lungs is matched to carbon dioxide production by the tissues.

The respiratory control system accomplishes this goal by adjusting pulmonary ventilation. The partial pressure of oxygen is kept at a level sufficient for tissue metabolism. The partial pressure of carbon dioxide in the tissues is kept at a level that ensures the maintenance of hydrogen ion concentrations within the limits necessary for protein function.

The regulation of respiration is a complex circuit of different processes. It may be influenced by oxygen and carbon dioxide content in atmosphere, by barometric pressure, by different pathological activities in the body etc.

The most important in humoral regulation of respiration is the tension (partial pressure) of oxygen (PaO_2) and carbon dioxide (PaCO_2) in arterial blood, but the interaction of these two components is quite complicated.

The influence of arterial CO_2 partial pressure on cerebral auto regulation (CA) is well known. It has been characterized in the frequency domain [2]. The PaO_2 also affects the breathing rate and oxygen assimilation. The deficiency of oxygen in the body may lead to hypoxia.

Nowadays due to the scientific and technical progress, air pollution increase, climate change, wide consumption of tobacco and allergy there is an increase in the numbers of conditions related to respiratory system. The most frequent conditions related to the respiratory system are: acute laryngitis, acute tracheitis, acute and chronic bronchitis, bronchial asthma, pleuritis, lung-cardiac insufficiency, bronchoectotic illnesses, and abscesses. It makes the effective treatment of respiratory organs and use of appropriate methods for the illness prevention a relevant issue

One of such methods includes special trainings to strengthen respiratory muscles, to enlarge the mobility of the chest and diaphragm, to increase the elasticity of pleural membranes, to improve the mechanisms of breathing regulation and movement coordination. The depth and frequency of breathing to some extent can be changed voluntarily. It represents a basic breathing training.

Previous work [3] has shown respiratory rate to have powerful physiological effects, for example, on cardiac baroreceptor sensitivity (BRS) independent of direct effects on arterial blood pressure (ABP). Physiological studies have employed various controlled respiratory rates in the spectral

analysis estimates of, for example, cerebral auto regulation (CA) using 6 breaths/min [4, 5], and cardiac BRS using 15 breaths/min [3]. However, work using the Valsalva and Mueller manoeuvres [6, 7, 8] has shown that changes in intrathoracic pressure can have a strong influence on the cerebral blood flow velocity (CBFV) response to transient changes in ABP. As the changes in intrathoracic pressure are likely to differ at different breathing rates, we postulate that this may influence estimates of cardiovascular functions.

To date, it is not clear what the effects of synchronized breathing at lower rates might be on cardiovascular functions. Breathing at different frequencies will induce oscillations in ABP that will change the heart work. These considerations led to the main hypothesis of our present study that synchronized breathing at different rates (e.g. 6 breaths/min) will have a significant influence on cardiac functions with results obtained during spontaneous breathing. Eames et al. [9] consider that the rate 6 breaths/min is the most effective.

Different controlled respiratory rates have been used in physiological studies where CA [4, 5] or cardiac BRS [7] have been measured. Disproportionately large changes in CBFV relative to the change in ABP have been recorded during the release phase of the Valsalva manoeuvre [6] and, on a smaller scale, changes in intrathoracic pressure during normal breathing may also add to CBFV variability on a breath-by-breath basis independent of their effects on ABP. Other sources of CBFV variability could be associated with systemic changes in mean PaCO₂ or oxygen tension, central modulating mechanisms, intrinsic cerebral vasomotion or mental activation [10-12]. Controlled respiratory rates might potentially control some of these variables by reducing the randomness of the respiratory effects and by 'clamping' mental activation through concentration on the light-emitting diode.

In other studies, changes thought to reflect impairment of CA with mean PaCO₂ levels have been seen using transfer function and time domain analysis when partial end tidal volume of CO₂ increased by 5 mmHg or more [2, 13]. Coherence function and gain frequency response increased for frequencies below 0.05 Hz, and phase frequency response decreased in the frequency ranges 0.02-0.1 Hz [2] and 0.07-0.20 Hz [13]. The coherence functions for the different controlled respiratory frequencies were significantly different from one another at the fundamental respiratory frequencies and their multiple harmonics, and the coherence function for all of the controlled respiration data was periodically higher and lower compared with the data recorded with spontaneous respiration. The observation showed that at 6 breaths/min, in contrast with the other respiratory frequencies, the peak in coherence at the fundamental frequency was lower than its first harmonic, could be interpreted as a sign of auto regulation in that frequency range that is less effective with increasing frequency.

The effect of phase is incorporated in the time domain measures. The step responses suggested that, in response to

a step in ABP, CBFV would subsequently fall towards baseline in slightly less than 5 s in all recordings, consistent with active CA, as reported from previous observations [14]. The step responses were characteristic of improved CA [14], with decreasing CO₂ end tidal volume, associated with the increasing respiratory rate, although the effect of respiratory rate alone was just not significant [4].

It was proposed that during HA adaptation, hypometabolism was developed as a mechanism to cope with the hypoxic stress. Such hypometabolism was also observed in fMRI studies involving gustatory stimulation [15] and cognitive performance [16]. There are also data indicating reduced amount of HA group gray matter volumes at bilateral insula [6] which points to its reduced functionality among the HA group. In authors' opinion one plausible interpretation would be that such reduced functionality contributes to the reduced ventilation associated with long term HA adaptation, in contrast with the hyperventilation typically experienced by new comers.

The goal of our research was to study some peculiarities of respiratory and cardiovascular systems of high altitude residents in Armenia.

2. Methods

Participants in the current study included 40 students from Vardenis (Armenia, 2000 m above the sea level) divided into 2 groups: I – 13-14 years old, and II – 15-17 years old. We have studied the breathing rhythm, chest circumference during quiet and deep breathing, lung vital capacity, erythrocyte amount, hemoglobin concentration, colour index, systolic, diastolic and pulse arterial pressure, before and after trainings. The control groups included 23 students of the same age from Stepanavan (1300 m above the sea level). The appropriate parameters were investigated.

The researched students should go through two months of trainings on controlled breathing. During the training the participants should make 6 breathing movements per minute, three times a day. Study of appropriate health parameters was done after the training period.

Significance of received data was determined by statistical analysis through package of SPSS programs (SD \pm 0.05). The entire research was carried out in accordance with Universal Declaration of Bioethics and Human Rights.

3. Results

Our data (see table 1) showed significant differences between the control and experimental student groups (see the table). The basal breathing rate in control groups was 16.33 ± 0.41 breath/min and 15.09 ± 0.34 breath/min. In the experimental groups it was respectively 19.25 ± 0.93 ($p < 0.05$) and 23.22 ± 0.74 ($p < 0.05$) breath/min. So a significantly increased rate of breathing in students from high altitudes was identified. After the training period the breathing rate of students from both experimental groups has significantly decreased to 14.50 ± 0.54 ($p < 0.05$) and 16.89 ± 0.42 ($p < 0.05$), and became almost the same in comparison with control

groups.

As the table shows there are significant differences in the erythrocyte amount, and hemoglobin concentration between control and experimental groups. The colour index of control group was within norm and in experimental groups at their minimal level. There are also significant differences in chest circumference during quiet and deep breathing.

The differences of lungs vital capacity in control and experimental groups are not significant, but nevertheless this parameter is too low in the experimental groups. In many cases, the biochemical changes in response to high altitude exposure are so striking that almost everything is statistically significant when compared to baseline. However, uncovering the biological relevance of those alterations remains a challenge. Relatively small (and *statistically* insignificant) changes in the steady-state concentration of biomarkers and signaling molecules may

be associated with *biologically* significant changes in physiology, in particular when regulatory circuits are operating at their limits. In other cases, statistically significant changes from baseline may simply indicate that the system is operating at a different set point (which may still be well within the regulatory range) [17].

Our data suggest that the bodies of high altitude residents possess mechanisms for adaptation to high altitude, for example high rate of breathing without changes of breathing volume. However the blood hemoglobin saturation is around the normal level, which means that there is also another mechanism underlying the adaptation process.

The students from experimental groups in comparison with students of the same age from the control groups had a significantly higher level of systolic and diastolic, and also pulse pressures, which may suggest the myocardium overloading. After two month of trainings the decrease in systolic and diastolic, and also pulse pressure was identified.

Table 1. Some parameters of pupils living at low (1300 m above the sea level) and high (2000 m above the sea level) altitudes.

Investigated parameter	Number of the group	Control	Experimental groups before training	Experimental groups after training
Breathing rate (breath/min)	I	15.78±0.36	19.25±0.93*	14.50±0.54*
	II	15.09±0.33	23.22±0.74*	16.89±0.42*

	II	37.72±1.59	48.91±2.11*	35.27±1.17*

Medical examination revealed few cases of cardiopulmonary sickness in both experimental groups. 4 of investigated 16 students of the first group had sinus tachycardia, 2 – respiratory arrhythmia, 3 – myocarditis and hypoxia, and 1 – right bundle-branch block.

For 20 investigated students from the second group the following was determined: 2 cases of sinus tachycardia, 1 – respiratory arrhythmia, 1 – myocarditis and hypoxia, 1 –

focal blockade with myocarditis and hypoxia, 1 – right bundle-branch block, and 1 – cardiac rhythm and conduction disturbance.

After the training period in the first group 1 case of respiratory arrhythmia, 1 case of sinus tachycardia was identified with 1 case of myocarditis and hypoxia changed to respiratory arrhythmia. All other students had no deviations. In the second group 1 case of sinus tachycardia

had changed to sinus arrhythmia, and 1 student had respiratory arrhythmia. So, the trainings on voluntary decrease in breathing rate had a positive effect.

Fig. 1-4 presents the ECG results of four students from two experimental groups before and after training.

Fig 1. ECG of the patient B.V. (I group). I, II, III, aVR, aVL, aVF, V₁, V₂, V₃ – appropriate lead. a – before training (the patient had respiratory arrhythmia), b – after training (the patient has no deviations).

Fig 2. ECG of the patient M.M. (I group). I, II, III, aVR, aVL, aVF, V₁, V₂, V₃, V₄, V₅, V₆ – appropriate lead. a – before training (the patient had right bundle-branch block), b – after training (the patient has no deviations).

Fig 3. ECG of the patient H.M. (II group). I, II, III, aVR, aVL, aVF, V1, V2, V3, V4, V5, V6 – appropriate lead. a – before training (the patient had sinus tachycardia), b – after training (the patient has no deviations).

4. Discussion

Barometric pressure falls with increasing altitude whilst the percentage of oxygen within the atmosphere remains constant. The consequent reduction in inspired oxygen impairs physical performance and may even threaten survival [18]. Graded and continued altitude exposure permits acclimatization, a progressive tolerance to hypoxia traditionally ascribed to cardiopulmonary and hematological responses that support global convective oxygen delivery [19]. These changes tend to reduce the gradient of oxygen partial pressure from ambient air to tissues [20] by increase of erythrocytes amount, systolic volume and hemoglobin concentration, which was shown

also in our studies. It was reported that peripheral physiological parameters, especially hemoglobin concentration, adapt very quickly to hypoxia/normoxia changes in the scale of weeks [21].

However, such responses do not provide a full explanation of the acclimatization process given that exercise tolerance remains limited even though arterial oxygen content returns to sea-level values [22, 23]. Furthermore, genetic selection pressure amongst high-altitude residents of the Tibetan Plateau (*in situ* for >20,000 years) favours lower rather than higher levels of oxygen-carrying hemoglobin [24, 25]. Finally, the marked inter-individual differences which exist in the ability to adapt to hypoxia sometimes are not explained by differences in arterial oxygen content [22]. Changes in

tissue oxygen handling, mediated in part through changes in the microcirculation and in mitochondrial oxygen use, are increasingly considered more important to the development of hypoxia tolerance than is the augmentation of its global convective delivery [23, 26, 27].

Significant correlations were found between specific aspects of pulmonary function (IRV & ERV) and BOLD signal variation at specific brain regions [28]. These correlations indicate the contribution of specific aspects of pulmonary function to cerebrovascular response (CVR). It seems that IRV had a wide influence on BOLD signal across multiple brain regions, not only in cortices involved in respiratory modulation (e.g., the insula, thalamus, and the precentral cortex), but also other cortices such as the fusiform cortex. The HA group indeed showed a larger IRV than the control group, while other aspects of pulmonary function maintained at a similar level [28]. In authors' opinion, it could be possible that it took a longer time for the oxygenation level of the HA group to reach peak, considering that the HA group had similar levels of respiration rate and hemoglobin concentration with the only observed difference at IRV; and this delay was eventually reflected in the delay of BOLD signal. It could also be related to the involvement of these brain regions in respiratory modulation.

As the study of a numbers shows, adaptation to high altitude describes changes that have occurred over a number of generations as a result of natural selection in a hypobaric hypoxic environment, and this can be observed in some groups of high-altitude residents [29]. The mechanisms responsible for such adaptation probably involve alterations in the control of breathing [30, 31].

It's known that the cardiovascular responses to voluntary delay of breathing are defined by interaction of different reflexes between lung vessels and mechano- and chemoreceptors of reflexogenic zones [3, 32]. Significant role in these interactions have changes of pressure in lungs, chest and abdominal cavity, which influences at the venous flow into the heart, and arterial pressure during breathing delay. Delayed deep breathing decreases the pressure in the chest and facilitates venous flow to the heart. Besides the accumulation of carbon dioxide in organism during breathing delay leads to extension of coronary vessels, and therefore improves myocardium delivering.

After controlled breathing trainings all investigated parameters became comparable with the same parameters of the control group. Therefore the method of voluntary decrease in the breathing rate is effective for the students living at high altitudes. Obviously after breathing trainings the adaptive mechanisms of metabolism and activity of aerobic breathing ferments are changed, which lead to the new level of oxygen delivery, and consequently to changes of oxygen delivering organs and systems. It is confirmed by positive correlation of breathing with decrease in sickness, improvement in heart work, physical and mental capacities. Practically the volitional control of breathing leads to positive changes in cardiovascular system. In summary, our

results suggest the possible contributions of pulmonary functions in cardiovascular reaction.

Vardenis region lies at 2000 m above the sea level (atmosphere pressure 809.92 mbar): It is important to note that today Vardenis out-patient clinic has 468 patients registered with ischemic heart disease, 678 patients with hypertension, 60 patients with acute bronchitis, and 29 patients with bronchial asthma. Most probably there are more unregistered people with arterial blood pressure oscillations.

The control of breathing can be divided into chemoreflex and non-chemoreflex drives to breathe. Non-chemoreflex drives (e.g. wakefulness drive, voluntary cortical drive, hormonal factors) have never been measured in highlanders, while a single study of acclimatization in lowlanders showed that these drives remain unchanged from sea-level values after 5 days of high altitude exposure [33]. Chemoreflex drives to breathe can be further divided into central and peripheral drives. Both central and peripheral chemoreceptors respond to changes in hydrogen ion concentration ($[H^+]$) in their immediate environments [34, 35], while peripheral chemoreceptors are also responsive to changes in PO_2 via hypoxia-mediated changes in their $[H^+]$ ion sensitivity [36, 37]. As a result, highlanders have induced acute changes in PO_2 and PCO_2 and measured the ensuing changes in ventilation to assess the chemoreflex control of breathing [38].

5. Conclusion

The cardiovascular system is an essential link in the transport of oxygen from the air to the mitochondria, and it therefore has an important role in acclimatization and adaptation to the oxygen depleted environment of high altitude. Using of the method voluntary optimal changes in breathing rate it may be possible to improve the adaptive mechanisms of high altitude residents, and health of patients with cardiovascular diseases.
