Abstract: Background: Hepatitis B and C viral infections continue to constitute major global health problems and are responsible for most liver related deaths. This study is carried out to reveal the hepatitis B and C single and co-infection patterns among emergency patients and their possible liver outcomes. Methods: Two hundred and eighty-eight (288) patients on initial visit from casualty unit were routinely screened for hepatitis B and C viruses over a period of two years in the haematology department. Diaspot one step enzyme immunoassay rapid kits for hepatitis B surface antigen (HBsAg) and anti-HCV respectively were used. HBsAg and anti-HCV seroprevalence and possible co-infections were evaluated using descriptive statistics of SPSS version 17 and expressed in mean and standard deviation, and male: female ratios. Results: Of the 288 research volunteers, 8.68% and 1.74% were positive for HBsAg and anti-HCV respectively. 1.04% was HBV and HCV co-infected. The overall mean age and male: female ratio were 44.4±17.3 years and 1.4:1 respectively. Lower mean age and higher male: female ratios were observed in HBV and HCV population. HCC remain the major liver outcome in HBV-infected and HBV/HCV co-infected research subjects. Conclusion: Hepatitis B and C viral infections still remain a major public health problem globally. There is need for continued aggressive advocacy on 'Know your HBV and HCV status' to reduce the scourge of these infections especially in rural and resource-limited settings where problem of poverty and ignorance have contributed to development of liver complications in these patients.

Keywords: HBsAg, Anti-HCV, HCC, Seroprevalence, Male: Female Ratios, Gender Differences

1. Introduction

Hepatitis B virus (HBV) infection is a blood-borne disease of clinical importance and global health problem. Hepatitis B virus is a member of the Hepadnaviridae family and a DNA virus with partially double-stranded DNA and a core antigen surrounded by a shell containing hepatitis B surface antigen (HBsAg) and other antigenic components of diagnostic importance [1]. HBV is the leading cause of chronic liver disease and liver-related deaths worldwide with the majority of these cases occurring in areas of Africa and Asia.

Transfusion of blood and blood products, circumcision, social demographic factors, and medical and surgical risk factors have been implicated as factors associated with HBV transmission [2-7].

HCV is another major public health problem worldwide. It is an envelope virus with a single-stranded RNA genome and a diameter of about 50nm. HCV belongs to the genus Hepacivirus in the family of flaviridae. Most hepatitis C viral diagnosis has been on the basis of detectable antibodies to the virus in human serum or plasma [8-9]. Direct percutaneous inoculation is the most efficient mode of transmission of

HCV, but sexual, household, occupational, and vertical transmission may also be important.

Aside from human immunodeficiency virus (HIV), hepatitis B virus (HBV) and hepatitis C virus (HCV) constitute a major public health challenge globally and especially in sub Saharan Africa. It has been documented that HBV and HCV are the most common causes of liver diseases globally affecting approximately 350 million and 170 million people respectively [10-12]. In fact, according to World Health Organization (WHO), more than 1 million people die each year from disease caused by HBV and HCV while most of those infected are unaware of their status thereby increasing the risk of developing the risk of liver disease and transmitting the viruses to others. Africa has been reported to be the region with the largest number of chronic carriers of HBV after Asia and has been considered a region of high endemicity. Although the exact disease burden for HBV is difficult to assess due under-reporting and inaccurate records, about 70-95% of the adult population in Africa show evidence of past exposure to HBV infection and the estimated seroprevalence ranges from 6-20% [13-14]. The prevalence of HBV infection in Nigeria was reported to be in the range of 2.4-18.4% [15-17]. On the other hand, HCV has a prevalence of 5.3% and an estimated 32 million people infected with HCV in Sub Saharan Africa making it the region with the highest burden of the disease in the world [18]. In Nigeria, previous studies recorded a prevalence of anti-HCV in the range of 3.6% to 5% [19, 20].

HBV and HCV share a few similarities like their mode of transmission, hepato-tropism and the ability to cause chronic infections that may lead to the development of liver cirrhosis and hepatocellular carcinoma (HCC) [21-23]. Although there are some differences in the geographical distribution of the two viruses HBV is more prevalent in Far East, Sub-Saharan Africa, and Southern America with 2%-15% of populations infected, whereas HCV is more prevalent in Asia, North-Africa and Europe with 2.5%-10% of population infected), they quite frequently co-exist especially in countries at high endemicity for one or both viruses and among patients with a high risk of parenterally transmitted infections. The estimated global prevalence of HBV/HCV dual infection is approximately 5%-20% in HBsAg positive patients and 2%-10% in HCV positive patients, with a quite different geographical distribution, as reviewed by Caccamo *et al* [24]. Esan *et al.* reported a prevalence of 0.15% among pregnant women in southwest Nigeria [25].

Studies indicate that HBV and HCV co-infection is associated with increased risk of worse clinical outcomes such as advanced fibrosis or cirrhosis, decompensation, hepatocellular carcinoma, and transplantation compared with HCV mono-infection [10, 12, 26-30] but this co-infection is largely under reported in Africa despite its severe outcome and especially the risk individual infections pose to health workers in the laboratory and emergency department of a health facility. It is against this background that we have conducted this study to obtain an evidence-based data showing the single and co-infection patterns of hepatitis B

and C viral infections among emergency patients reporting to our laboratory for HBV and HCV screening.

2. Study Methods

2.1. Study Population

The study population for this research study were two hundred and eighty-eight (288) emergency patients reporting to our laboratory for whom hepatitis B and C viruses screening were requested. Patients with already known status or those with Hepatitis B Virus vaccination within one week were excluded from the study.

2.2. Study Location

This study was carried out at the Haematology department of the Federal Teaching Hospital (FETHI), Ido Ekiti, Nigeria. FETHI was located in Ido Ekiti, the principal town in Ido Osi local government area of Ekiti state with an estimated population of 107,000. It is geographically located in the northern part of Ekiti state which covers an estimated total area of 6353km², 2,453square mile and an estimated population of 2,737,186, where the routes from Kwara and Osun states converge. FTH, Ido Ekiti was upgraded in 2006 to formerly as a Centre for HIV/AIDS and other blood-borne infections including viral hepatitis B and C viruses referral, diagnosis and treatment in Ekiti State and serving five contiguous states. The Teaching Hospital since then has been offering diagnosis, prophylactic and therapeutic treatment for infected patients.

2.3. Study Period

This research study was carried out over a period of twenty-five months (February 2012 to February, 2014). Whole blood samples were collected following informed consent as part of the ethical consideration as the research participants presented themselves at our facility. Plasma/ sera were separated immediately and tested for HBsAg and anti-HCV antibody within 4 hours of separation.

2.4. Study Design

2.4.1. Hepatitis B and C Viral Testing

All patients who reported to our laboratory for emergency screening based on suspected hepatitis B and C viral infections were screened with Diaspot enzyme immunoassay (EIA) rapid diagnostic kits using plasma/serum separated from whole blood/clotted blood sample. Quality of results was established through the use of known HBV-infected volunteer and analyst's control.

2.4.2. Statistical Analysis

Data were analyzed with the descriptive analytical tool of the SPSS (Statistical Package for Social Sciences, Chicago, IL) version 17 software. Results were expressed in tables as means and standard deviations.

3. Results

288 research participants who gave informed consent had their blood samples taken for analysis. The overall mean age and male: female ratio of research participants were 44.36 ± 17.28 and 1.4:1 as shown in Table 1. Twenty-two (22) in all were seropositive for HBsAg giving a seroprevalence of 8.68%; only five (5) were seropositive for anti-HCV, that is, anti-HCV seroprevalence was 1.74%. The HBsAg and anti-HCV were detected in only three (3) among the studied population giving the lowest seroprevalence of 1.04% for HBV/HCV co-infection observed in the study as shown in Table 2. The mean age and male: female ratios of infected patients according to the viral status were presented in Table 3. The mean age and male: female ratio for HBV-infected emergency patients were 39.1 ± 17.2 years (inter-quartile age range 17.2 -51.0 years) and 6.3:1. That of HCV-infected emergency patients were 30.2 ± 10.9 (inter-quartile age range: 18.5 -39.5 years) and 4:1 respectively. Finally, table 4 showed the HBV and HCV single and co-infection patterns among the emergency patients according to sex. 19 (86.4%) out of the 22 HBV-infected and 4 (80%) out of the 5 HCV-infected cases were males. The reverse was observed among HBV/HCV co-infected counterpart where two female patients (66.7%) had dual infection.

Furthermore, among the 22 research subjects positive for HBV, only eight (36.36%) developed hepatocellular

carcinoma and four (18.18%) had transit liver cirrhosis while ten (45.46%) were chronic carriers of HBV infection. No case of liver complication was noted among the anti-HCV positive research subjects.

Table 1. overall mean age $\pm$ sd and male-female ratio of research participants.

Research participants	Mean age(yrs)	Male	Female	Overall Male-Female Ratio
288	44.4 ± 17.3	168	120	1.4:1

Table 2. Hepatitis B Surface Antigen And Anti-HCV Seroprevalence Among Emergency Patients.

Viral infection	Total No	No Positive	Prevalence (%)
HBsAg	288	22	8.68
HBsAg& HCV Ab	288	3	1.04
HCV Ab	288	5	1.74

Table 3. Mean Age $\pm$ Sd And Male-Female Ratio According To Viral Status.

HBsAg	HCV Ab	Mean $\pm$ SD (yrs)	Male-Female Ratio
Positive	Negative	39.1 ± 17.2	6.3:1
Negative	Positive	30.2 ± 10.9	4:1
Positive	Positive	39.0 ± 12.3	1:2

Table 4. hbv and hcv single and co-infection pattern among emergency patients according to sex.

SEX	HBsAg	% HBV	Mean age	HCV Ab	% HCV	Mean age	HBV/HCV	% HBV/HCV	Mean age
	Positive	Positive		Positive	Positive		Infection	Infection	
	(n)	(%)	(Yrs)	(n)	(%)	(Yrs)	(n)	(%)	(Yrs)
MALE	19	86.4	39.7 ± 16.3	4	80.0	32.8 ± 9.3	1	33.3	53.0 ± 0.0
FEMALE	3	13.6	35.3 ± 9.7	1	20.0	20.0 ± 0	2	66.7	41.5 ± 11.3

4. Discussion

The results of this study showed that 168 male subjects (58.3%) and 120 female subjects (41.7%) participated in the research study resulting in overall male: female ratio of 1.4:1. The overall mean age of research participants was 44.36 ± 17.28 years (inter-quartile age range: 31.0-58.0 years). Our findings revealed HBV and HCV seroprevalence of 8.68% and 1.74% respectively and corresponding mean age and male: female ratios of 39.1 ± 17.2 years (inter-quartile age range 17.2 -51.0 years), 6.3:1 and 30.2 ± 10.9 (inter-quartile age range: 18.5 -39.5 years), 4:1 respectively among emergency patients. These research outcomes were slightly higher than HBV seroprevalence reported by Tuba and his co-researchers [31] and Gabor *et al* [32] who reported 5% among Turkish critically ill emergency patients and those from emergency department of Johns Hopkins University respectively. Anti-HCV seroprevalence among emergency patients reported in this study is more than eleven times that reported by Esan *et al.* [25] among

pregnant women attending the antenatal clinic of this same institution. Esan and his colleagues reported 0.15% among pregnant women while the finding among emergency patients was 1.74%. This suggests other risk factors such as the use of injection drugs, percutaneous infections, alcoholism and smoking, and to a lesser extent sexual risk behaviour which is more prevalent among men may be responsible for this. Gender difference in HBsAg and anti-HCV antibody prevalence was clearly shown. We found that the HBsAg and anti-HCV antibody prevalence was significantly higher in males than females ($p < 0.01$). Of the HBV-infected population, nineteen (86.4%) were males and 3 (13.6%) were females with mean age of 39.7 ± 16.3 yrs and 35.3 ± 9.7 yrs respectively. The results of this study is concordance with two recent large series study from Greece and New Zealand and another by Pei-Kwei and his co-researchers which showed a higher HBsAg prevalence in males than females [33-35]. However, this is in contrast to the findings in Taiwan patients where HBsAg prevalence between genders was not significantly different in

epidemiologic studies in Taiwan [36-38]. The prevalence of HBV/HCV co-infection was 1.04% with male: female ratio 1:2 and mean age 39.0± 12.3 (inter-quartile age range: 30.0-53.0 years).

Moreover, more than 45% (45.46%) of the 22 emergency patients positive for HBsAg were chronic carriers of hepatitis B, some of which were unaware of their status until tested and were patients that were screened for hepatitis B viral infection during their initial visit. Of the remainin twelve (54.54%), four (18.18%) had transit liver cirrhosis and eight (36.36%) developed hepatocellular carcinoma (HCC). This showed hepatocellular carcinoma to be most common hepatic disease that results from HBV infection. We could not ascertain the frequency of HCC in the anti-HCV positive emergency patients. It seems not to be a common occurrence here. Of the three patients who had HBV and HCV co-infections, only two (one male and another female patients) had evidence of hepatic trauma. We can probably attribute the development of HCC in these patients to dominance of HBV infection. HBV-HCV infections in this other female patient could not be confirmed as there is no observed hepatic disease. The outcomes of this research corroborated the report of the International Agency for Research on Cancer in 1994. The agency analyzed multiple cohort and case control studies and reported that there was sufficient evidence in humans for the carcinogenicity of chronic HBV infection [39]. The relative risk of HCC among people infected with HBV ranges from 5-49 in case control studies and 7 to 98 in cohort studies [40]. Recently, a nomogram was introduced for the calculation of the risk of developing HCC based on risk factors such as male gender, older age, family history of HCC, use of alcohol or tobacco, high serum HBV DNA levels, HBV genotype C, co-infection with HCV, HIV or hepatitis delta virus, increased serum alanine aminotransferase and presence of liver cirrhosis[41-42]. These tools can be very helpful for the clinicians while counselling patients regarding preventive measures and potential strategies to decrease risk of HCC.

5. Conclusion

Hepatitis B and C viral infections still remain a major public health problem globally. There is need for continued aggressive advocacy on 'Know your HBV and HCV status' to reduce the scourge of these infections especially in rural and resource-limited settings where problem of poverty and ignorance have contributed to development of liver complications in these patients. All tiers of government in Nigeria, and by extension, every nation should have a well-established public enlightenment, screening and vaccination programmes. All factors that can contribute to increased risk of hepatocellular carcinoma in infected patients should be avoided especially in men.
