---

**Abstract:** Field investigations in the western part of Mukuru area indicate intense structural imprints and high HT/HP metamorphism, and some magmatism. The rock units in the area include migmatitic gneisses, granulites, amphibolites, schists, charnockites, epidiorites and granites. The charnockites which are common in the shear zone and boundary areas appear to mark the end of magmatism. However, relicts of magmatic rocks mapped at Ubong Community in the study area suggest earlier magmatism. The metamorphic rocks are strongly deformed in a N-S to NE-SW direction with ghost structures, pinch and swell structures, pytygmatic veins, showing evidence of extensional tectonics. No visible contact relationship between the migmatitic gneisses and schists was observed. Diagnostic metamorphic structures like fine banding/layering of alternating dark- and light-coloured layers are conspicuous in gneisses and some amphibolites while schistosity and deep weathering are present in schists. The geodynamic features prevalent in Mukuru area are deformation and metamorphism. They indicate a possible petrogenetic link to southern Obudu Plateau in the north, western Cameroon in the east than Bansara in the west.

## 1. Introduction

Mukuru sheet is located east of Boki Local Government Area, Cross River State, Nigeria. The western part of the study area is bounded by latitude  $6^{\circ} 10'$  to  $6^{\circ} 30'$  N and longitude  $9^{\circ} 00'$  to  $9^{\circ} 11'$  E and flanked in the NE-SW by an elongated rifted depression, the Benue Trough and on the southeast by the prominent Cameroon Volcanic Line (CVL) (Ekwueme, 1987; Edet et al., 1994) (Fig.1) Thick equatorial rainforest of Oban Massif and Bansara area and the rugged Obudu Plateau topography have remained a barrier to detailed geological studies (Egesi and Ukaegbu, 2010 a&b). Geologically, it is part of western prolongation of the reactivated Precambrian Pan-African tectonothermal belt of the West African craton to the left and Gabon-Congo Craton (GCC), to the east (Ukaegbu, 2003). The area is predominantly composed of highly deformed continuous N-S trending polymetamorphic rocks comprising migmatitic gneisses, schists, amphibolites and undeformed charnockites and less of eclogites, epidiorites and granites. The area was probably subjected to strong collision process, which gave rise to high pressure, high temperature upper amphibolite-granulite rocks, with strong imprints of the N-

S and NE-SW Pan-African Orogeny. This research attempts, to present insight into petrogenetic and geotectonic history of the Mukuru area of the Bamenda Massif.

## 2. Geological Setting

Mukuru sheet (305 NW & SW) are parts of the larger Bamenda Massif of the Cameroon. The rock types which

form the boundary area with Bansara are charnockites. The charnockites form massive chain of hills, from Buanchor to Bakum as far as Okorshie in southwestern parts of Obudu area and separate the granulites rocks of Kanyang, Wula, Bakalum, and Bamba areas.(Fig.2) The amphibolites form large exposures at Okiro and Ubong areas, showing outcrops of epidorites between Okiro, Ubong and Bakum areas. The amphibolites become schistose northwards at Ofambe and Begiagbah areas where they form high plateaux and hills. At the Cross River National Park, Butatong field office, there is an exposure of schists which have been highly deformed and weathered, extending into Bemí River which contain alluvium deposits. The Bemí River flowing in a N-S direction forms the buffer zone boundary with none buffer zone. The river is about 30km to Okwangwo and 60km to Okwa area boundary with Takamanda National Park in Cameroon. The general trend of structures follows the other already established patterns in other parts of the reactivated Basement Complex of Nigeria (Orajaka, 1964; Rahaman, 1976; Grant, 1978; Ekwueme, 1987; 1994, Ukaegbu, 2003; Ukaegbu and Oti, 2005, Egesi and Ukaegbu, 2010 a&b). The metamorphic rock units consist of migmatitic gneisses with structures

like folds (open, isoclinal, gentle to tight), granulite complex, schists and amphibolites. The granulite metamorphism probably was repeated/polycyclic, leading to formation of retrogressed granulites and amphibolites. This is similar to the classical regions for poly metamorphism like the Lewisian Complex of NW Scotland and the Lewisian Complex of West Greenland, with the following metamorphism episodes:-

**2.1. Petrology**

Mukuru sheet 305 NW and SW consist of minor biotite granites at Ubong area, extensive charnockites from Buanchor to Olum, Bakum as far as Okorshie in the north which is in Obudu sheet 291 SW (Figs. 4 and 5).

**Fig.4a.** Biotite Granite at Ubong area

**Fig.5b.** This photomicrograph is porphyritic texture with brownish Feldspar and quartz ( X 40) .

The amphibolites exhibit black to dark green colour, and have medium to coarse-grained texture with well developed foliation at Ubong, Okiro Ubang, Begiagbah and Bamba areas (Figs 6,7,8,9 and 10). They are relatively massive and hard so that small-scale folds are rarely developed. The hornblende schists form highlands at Ofambe and Olum areas (Figs.11, 12 and 13). Schists are also extensive and deeply weathered and deformed on the lowland areas from Butatong to Okwangwo areas.

### 3. Structural Geology

The extensive charnockitic rocks seem to have terminated the massive igneous activities observed in Bansara area. The major structural features in Mukuru area is the Mbe mountain belt which includes Kanyang hills, Bakalum hills, Abuogbangante hills, Abumkpang hills Bamba hills, while Bakum hills, Begiagbah hills and Ubong hills are parts of Afi mountain. The rocks in the area are metamorphosed, deformed without any visible magmatic structures. However, biotite granites were mapped in a restricted occurrence at Ubong area which is in close proximity to the Bansara/Mukuru boundary areas (Figs 1 and 2).

### 4. Planar structures

The banding in the gneisses is irregular and foliation is well defined. Quartz and feldspars (perthites and anti-perthites) are pre-dominant and micaceous minerals are lacking in the amphibolites, and hornblende schists display a fine banding at some locations and are less conspicuous in amphibolites than in schists. Figs 6,7,8 and 10. The migmatites consist of gneiss and a granitic component which form layers or veins with clusters of feldspar and quartz grains. Swirling folds and completely flow creep veins are evidence that these rocks were probably "plastic" (Figs 5 and 15).

## 5. Linear structures

Lineated, strongly schistose rocks which can help in the identification of the minerals present were mapped in the area. Hornblende and micas are common and these show segregation banding in the schists. The Mbe mountain belt, Buanchor hills, Bakum hills and several other highlands are in N-S to NE-SW trend which conforms with observed regional structures in Obudu area (Ekwume, 1987; Ukaegbu and Oti, 2005). The ghost structures in granulites is in a N-S trend at Kanyang. The linear feature in migmatites are fold axes which are in E-W direction at Bamba. The Bemi River courses flow N010°E is in N-S direction, and major faults lineaments are in a regional N-S directions (Figs. 20 and 21)

## 6. Discussion

Mukuru area consists mainly of metamorphic rocks. The late to post Pan-African intrusives are absent in Mukuru. The geology appears to be similar to that of southern Obudu (sheet 291) which also lacks abundant granites (Ukaegbu, 2003). The gneissoids were emplaced into the

metamorphic Basement Complex of Bansara/Mukuru boundary and also mark the terminal end of the Pan African event (Egesi and Ukaegbu, 2011).

The periphery of the Mukuru sheet is strongly defined by charnockitic rocks, which form highlands with exfoliation weathering of boulders, exposing fresh surfaces from the south Buanchor to Okorshie, in the north. The granulites do not extend to these charnockites on exposed surfaces, and they seem to demarcate the granulites terrain. There is no contact relationship between the migmatitic gneisses and schists revealed on the surface but spatial configurations of both rock types suggest that the schists may be relatively younger, and were probably supracrustals on the gneissic rocks. The amphibolites, which occurred as lense in granite gneisses at Agba Osokom in Bansara area, are relatively massive and hard to sample in Mukuru area. The rocks at Kanyang are granulite facies characterized by pyroxene while at Ubong/Okiro are amphibolite facies rocks with hornblende as the main component. Also, in the Ikpeshi area of Igarra schist belt southwestern Nigeria, rocks that have amphibolite facies mineralogy has been mapped by Faculty and students of the Department of Geology, University of Port Harcourt in 2009. The geodynamics features prevalent in the Mukuru area are deformation and metamorphism. They indicate a possible petrogenetic link to southern Obudu Plateau in the north, western Cameroon in the east than Bansara area in the west.

## 7. Conclusion

The structural relationships in Mukuru area are similar to those of Obudu Plateau but different from the Bansara area, in having granulites facies metamorphism, retrogressive metamorphism and amphibolites facies mineralogy. Deformation and metamorphism started earlier in the area and terminated with magmatism of the Bansara area. Rock types mapped in Mukuru have been classified on the basis of field, petrographical and mineralogical criteria as migmatitic gneiss, granulite, eclogite, migmatitic schist, amphibolites/hornblende schist, epidiorite and biotite granite.
