Abstract: An imperforate hymen is a congenital disorder where a hymen without an opening completely obstructs the vagina. A 16 year old, female, single with cyclic, lower abdominal pain, palpable supra-pubic mass and primary amenorrhea. Ultrasound show; well-defined echogenic fluid collection posterior to the urinary bladder, fluid with internal echoes in the uterine cavity the final diagnosis hematometocolpos due to imperforate hymen.

Keywords: Imperforate Hymen, Haematometra, Vagina, Ultrasound

1. Introduction

Imperforate hymen is at the extreme of a spectrum of variations in hymenal configuration. Variations in the embryologic development of the hymen are common and result in fenestrations, septa, bands, microperforations, anterior displacement, and differences in rigidity and/or elasticity of the hymenal tissue. Inspection of the external genitalia and anus are important components of the physical examination of the female neonate and child [1].

Affected newborns may present with acute urinary retention [2]. In adolescent females, the most common symptoms of an imperforate hymen are cyclic pelvic pain and amenorrhea; other symptoms associated with hematocolpos include urinary retention, constipation, back pain, nausea, and diarrhea [3].

Diagnosis, an imperforate hymen is most often diagnosed in adolescent girls after the age of menarche with otherwise normal development [4]. In adolescent girls of menarcheal age, the typical presentation of the condition is amenorrhea and cyclic pelvic pain, indicative of hematocolpos secondary to vaginal obstruction. An imperforate hymen is usually

visible on vaginal inspection as a bulging blue membrane [4]. If hematocolpos is present, a mass is often palpable on abdominal or rectal examination. The diagnosis of an imperforate hymen is usually made based purely on the physical exam, although if necessary the diagnosis can be confirmed by transabdominal, transperineal or transrectal ultrasound [3]. An imperforate hymen can also be diagnosed in newborn babies and it is occasionally detected on ultrasound scans of the fetus during pregnancy [4]. In newborns the diagnosis is based on the findings of an abdominal or pelvic mass or a bulging hymen [4]. Examination of the normal neonatal vagina usually reveals a track of mucus at the posterior commissure of the labia majora; an absence of mucus may indicate an imperforate hymen or another vaginal obstruction [2]. A similar condition, cribriform hymen, is diagnosed when the hymen contains many minute openings [5].

The differential diagnosis of imperforate hymen is from labial adhesions, vaginal atresia, vaginal agenesis, and transverse vaginal septum. However, the abdominal mass has to be diagnosed differentially from distal urinary bladder, ovarian tumors and neoplasms, mesenteric cysts, anterior

meningocele, reduplication of sigmoid and sacral tumors [6].

2. Technique

A low-frequency curvilinear or phased-array transducer or a linear high-frequency transducer may be used for visualization of the abdominal and pelvic structures. The transducer is initially placed in the transverse plane above the pubic bone. Visualization of the bladder may serve as a landmark for locating other pelvic structures. This common sonographic view will quickly identify abnormal anatomy when a mass is palpated in the lower abdomen. Acquiring images in the transverse and sagittal planes as well as defining all borders of each structure can achieve a thorough interrogation, both qualitative and quantitative. When urinary tract obstruction is suspected, obtaining views of the right upper quadrant and left upper quadrant of the abdomen allows for assessment of the kidneys. The kidneys may

demonstrate various degrees of hydronephrosis, where the calyces and the renal pelvis become distended and fluid filled in the pelvic view, the bladder may be observed for urine jets, indicating appropriate drainage of urine from the ureters. Finally, the bladder itself can be assessed for gross distension if there is bladder outlet obstruction [7].

3. Case Report

We report a case of 16 year old, female, single of Sudan origin that was seen in the ultrasound department with cyclic, lower abdominal pain, palpable supra-pubic mass and primary amenorrhea. A careful ultrasound assessment show; on transverse a well-defined echogenic fluid collection posterior to the urinary bladder = hematocolpos. On sagittal there is small amount of fluid with internal echoes in the uterine cavity = the final diagnosis hematometocolpos due to imperforate hymen. (FIG I, 2).

4. Discussion

In the embryological period, the lateral portion of the hymen originates from a fold of the urogenital sinus. The posterior part originates from the cells of the urogenital sinus, externally, and from Müller's duct, internally. Usually, at the 8th week of gestation, it partially ruptures in the inferior part of Müller's duct, remaining as a fold of mucous membrane around the entrance of the vagina. Failure of these events results in persistence of the septum [8].

Imperforate hymen is rarely diagnosed in the neonatal period, and most cases are presented to the gynecologist between the age of 11 and 15. Cyclical pelvic pain 2.5 to 4 years after thelarche, primary amenorrhea and a palpable pelvic mass represent the characteristic clinical symptomatology. Urological problems related to external compression of the bladder and ureter is also very common. Urinary hesitancy and dysuria are detected in as many as 58% of patients with hematocolpos. Although clinical examination is in most cases sufficient for the diagnosis of imperforate hymen, imaging studies are also necessary to confirm the presence of hematocolpos or hematometra [8].

Transabdominal USG is the commonest method used for that purpose [2-5]. However, in some occasions findings can be misinterpreted as a suspicious pelvic mass and provoke severe anxiety to a young girl and her family. In addition, to further clarify spurious findings of transabdominal USG and rule out possible associated congenital anomalies, other imaging or invasive modalities have been used such as CT scan, MRI scan and video laparoscopy [2-4]. All of them are very accurate in diagnosis of hematocolpos and hematometra, however, they are not considered to be cost-effective. Transrectal USG has also been reported as a method of evaluating pelvic anatomy in young girls with no sexual activity. Although, it has been quite accurate in diagnosis of hematocolpos, it is not considered to be an acceptable method for this age group, due to possible psychological implications [8].

The most common symptoms of an imperforate hymen are cyclical abdominal pain and urinary retention, usually presenting between the ages of 13 and 15 years (when menarche occurs) [9, 10]. There is primary amenorrhea but secondary sex characteristics are well developed. Because the vaginal outflow is obstructed by the non-perforated hymen, menstrual blood accumulates in the vagina (haematocolpos) and the uterus (haematometra). This may lead to mechanical effects on the urethra, bladder, intestines or pelvic blood vessels which can result in urinary retention, obstipation or edema of the legs [9, 11, 12]. Irritation of the sacral plexus or nerve roots can cause lower back pain [13]. Problems with intercourse are rarely mentioned, probably because most of the patients are still sexually inactive [14].

Treatment; before surgical intervention in adolescents, symptoms can be relieved by the combined oral contraceptive pill taken continuously to suppress the menstrual cycle or NSAIDs to relieve pain [15]. Surgical treatment of the imperforate hymen by hymenotomy

typically involves making cruciate incisions in the hymen, excising segments of hymen from their bases, and draining the vaginal canal and uterus [16]. For affected girls who wish (or whose parents wish) to have their hymens preserved, surgical techniques to excise of a central flange of the hymen can be used [17]. The timing of surgical hymen repair is controversial: some doctors believe it is best to intervene immediately after the neonatal period, while others believe that surgical repair should be delayed until puberty, when estrogenization is complete [18].

5. Conclusion

Girls with acute urinary retention particularly those who have not yet stated menstruation or delayed in their mid-teens, imperforate hymen should be considered as a possible differential diagnosis.
