Abstract: Chylothorax is defined as accumulation of chyle in the pleural space. Various aetiologies have been identified. Direct injury to the thoracic duct following gunshot injury is rare. When it occurs close to the point of entry into the confluence of the internal jugular and subclavian veins, it can lead to massive chylothorax with devastating consequences. A case of gunshot to the root of the neck with massive chylothorax with haemodynamic instability is hereby presented.

Keywords: Chylothorax, Gunshot Injury, Thoracic Duct

1. Introduction

Chylothorax is defined as accumulation of chyle in the pleural space. Over 2 litres of chyle is said to be transported daily through the lymphatic channels. Therefore, damage or rupture of the thoracic duct can lead to massive accumulation of these fluid in the pleural space leading to haemodynamic and respiratory compromise [1-4]. Aetiologies of chylothorax has been classified as either traumatic or non-traumatic. The traumatic type causes direct damage to the duct which will lead to instant leakage in chyle or by damage to surrounding tissues around the duct that may result in inflammation and compression of the duct leading to blockage of the duct which will subsequently lead to rupture. Thoracic surgery is now said to be the leading cause of traumatic chylothorax with oesophageal surgery leading the way [5-7]. Penetrating chest injuries account for 0.2-3% of cases [8-9]. We present a case of gunshot injury to the left supraclavicular region with massive chylothorax which was refractory to resuscitation and conservative management.

2. Case Report

A 20-year-old man who was shot at the left supraclavicular region at a close range, was said to have bled at the scene of the incidence. Patient was rushed to a near-by hospital where he had a chest tube inserted which initially drained blood and air and subsequently kept on draining yellowish-milky fluid. Average drainage in 24hrs was in excess of 2litres. The patient was referred to our unit for further evaluation and management. At presentation he was in hypovolaemic shock and was immediately resuscitated and had a 0.5cm entry wound and about 1cm exit wound posterior to the neck. Within 24 hours on admission he drained about 2.2litres and went into hypovolaemic shock in which he was also resuscitated. Chest X-ray showed homogenous opacity of the left hemithorax with mediastinal shift to the right (see Figure 1).

Figure 1. Chest X-ray.

A diagnosis of post-traumatic high output chylothorax was made. He was kept on nil by mouth, intravenous fluid and antibiotics. Pleural fluid sample was sent for analysis and triglyceride was 183mmol/L. Had pleurodesis with tetracycline but there was no reduction in output. He was prepared for thoracotomy and ligation of the thoracic duct. Intraoperatively massive chylous effusion with residual tetracycline debris within the pleural cavity was discovered (see Figure 2).

Figure 2. After thoracotomy – massive chylothorax.

Exploration revealed an opening close to the point of entry of the thoracic duct into the junction between left subclavian and left internal jugular veins which was continuously draining chylous fluid (see Figure 3).

Figure 3. Artery forceps showing the point of injury.

Opening of the duct was ligated with surrounding tissues and fluid was noticed to have stopped draining. The pleural cavity was copiously irrigated with warm saline and thoracotomy wound closed in layers. Post-operative fluid drainage remained less than 100mls/24hrs of serous fluid and chest tube was removed on the 4th day post-op. He was discharged on the 7th day post-op. He was seen in the outpatient clinic in stable clinical condition.

3. Discussion

Isolated thoracic duct injury without any major vascular or tracheobronchial injury is said to be rare [10-12]. Even where it occurs, it is said to be overshadowed by other injuries intrathoracic injuries [13]. Worthington et al [9] reported an incidence of 0.06% in their series over a 13-year period. Our patient had a gunshot injury to the thoracic duct close to its entry into the confluence of the subclavian vein and internal jugular vein. The bullet miraculously missed most of the structures in the neck. He presented with massive drainage which is not surprising as this is the point of maximum amount of chyle, therefore, injury at this level is likely to lead to high output chylothorax. This massive drainage predisposed him to hypovolaemic shock twice under our care. The initial approach to chylothorax is conservative management which entails placing a chest tube to drain the pleural space, nil by mouth, medium chain triglyceride administration by mouth and institution of total parenteral nutrition if above measures fail. These have been reported to reduce the flow of chyle thereby allowing healing to occur [1, 14]. Our patient was initially placed on nil by mouth and chest drainage but never showed any sign of improvement as such we opted to pleurodesis him which has been advocated by some authors [15-17]. This also did not lead to reduction

in the drainage. For pleurodesis to be effective, it is important that full lung re-expansion is achieved after draining the fluid [18]. With this massive amount of fluid draining, it will be difficult to achieve full lung re-expansion as such the pleurodesis failed. The optimum time for surgical intervention is still not clear, some authors advocate persistent drainage of 2 weeks while others advocate one week [19-20]. The patient had surgery after 2 weeks of non-operative management with no significant improvement. We did a thoracotomy and ligated the duct close to the point of injury (close to the point of entry). We were able to achieve this because we could identify the duct at this level. At around this level it is advocated that ligation can be carried out at Poirier's triangle through a left thoracotomy [1, 21-22]. Our patient had an uneventful recovery and was subsequently discharged.

4. Conclusion

It was concluded that patients with thoracic duct injuries close to the entry of the thoracic duct into the internal jugular vein can have massive chylothorax that is likely to be refractory to conservative management and pleurodesis as such early surgical intervention is indicated. There is need for further research to ascertain the amount of drainage at presentation that will warrant urgent surgical intervention and to determine acceptable time to abandon conservative management.
