Abstract: Solar energy, though renewable, still has a handicap of heat storage, particularly for the solar water heaters with integrated storage. Indeed, these latter present a significant night cooling. The storage material nature can influence the lifespan of the storage tanks, the quantity of stored heat and its speed of restitution. We compare here five materials for the heat storage which are sand, concrete, clay, Phase Change Material (PCM) and water like element of reference for comparisons. As for the PCM used here, it is paraffin sold in the trade, though other materials admit an enthalpy of higher fusion. If during the diurnal heating, the PCM does not reach the highest temperatures, it is because received solar energy is used for its change of state. However, from a viewpoint amount of stored heat, PCM is the best view of its high latent heat. Also for well as night cooling, the PCM keeps the temperature elevated.

Keywords: Water Heating, Solar Energy, Integrated Storage Collector, Storage Material, Concrete, Sand, Clay, Paraffin, Water

1. Introduction

In the national and international context, solar energy is able to play a significant role in the energy saving and the environmental protection. Among the various applications of this renewable energy, solar water heater are most widespread because their simplicity and the high requirements out of domestic hot water. Usually, a solar water heater is composed of two major parts: the solar water collector (the panel) and the heat storage realized by a cumulus filled with water [1-3]. The transfer of heat between the two parts is done either by thermosiphon, or by forced water circulation. However, the problem of heat storage for the solar water heaters has still been raised despite all research efforts, for several decades. Often, the requirements out of hot water are shifted (in dephasing) compared to the solar contributions, on a scale day (day and night) and seasonal (summer and winter). The problem is even more serious (sensitive) for the integrated storage solar collectors (ISSC), especially for the flat ones. Indeed, their night

cooling, particularly in winter, brings down lower the temperatures and the performances in general in a significant way.

2. Bibliographical Study

The heat storage of the solar water heaters has been studied by several authors. Reddy [4] studied paraffin like material with phase shift MCP as a material of storage in a sensor with integrated storage. In the same way, Rabin et al. [5] investigated on hydrated salt with the same aim than the experiments of Reddy and developed a one-dimensional model to study the process of the system filling. They concluded that this type of system can yield a collection performance of approximately 66% during winter in Beer-Sheva, Israel, but that the use of such a system is likely to be limited to special applications, such as space and soil heating greenhouses in arid areas, during winter.

But the problem of heat storage still remains current. Thus, we contribute to solve these problems using

comment materials, which are cheap and with phase change.

Our integrated storage solar collector (ISSC) is composed of an absorber, a glazing, an insulator and a case [6-10]. Deteriorations of the ISSC often take place on the level of the absorber which at the same time plays the role of tank of storage of hot water. The attack is done by corrosion of its material inducing escapes thus and in consequence new expenses of replacement.

The tank storage, usually made of metal is subject to corrosion, is often treated by enameling, or made by stainless still and is protected by a magnesium bar (anodizing). Despite all these precautions, corrosion however occurs after a certain time.

To cure definitively this problem of corrosion, we recommend to exceed traditional storage of heat in the water contained in the metal tank and to replace this water by sand, concrete, clay etc. (cf § 2.1). In this storage, the heat exchanger containing some water is integrated there.

Oil should to be avoided, for safety to prevent fire breakouts reasons.

Paraffin and other materials with phase change will be presented in the paragraph 2-2.

2.1. Preliminary Thermal Data on Some Materials (Comparison Between Water, Sand, Concrete, Clay and Plaster)

A preliminary study on the storage material choice enables to make a selection. It is based especially on the thermal conductivity, the thermal specific capacity, the diffusivity and the effusivity (table 1). Our choice was focused on concrete, clay, sand and the water taken as reference. Plaster should to be avoided because it owns the weakest conductivity and thermal effusivity. Concrete and clay are interesting and moreover can be directly molded, thus doing without being the prone to corrosion and having an expensive metal tank.

Table 1. Properties of some materials- [11-15].

Materials	Density { ρ } (kg/m ³)	Thermal conductivity { λ } (W/m.K)	Heat capacity {cp} (J/kg°C)	Diffusivity {D} (10 ⁻⁶ m ² /s)	Effusivity {E} (J/m ² .K.s ^{1/2})
Concrete	2300	1,75	880	0.54	1940
Clay	1450	1.28	880	1.00	1220
Water	1000	0.607	4185	0.37	1590
Dry Sand	1650	0.27	835	0.20	760
Plaster	820	0.25	1000	0.30	453

2.2. Preliminary Thermal Data on Some Phase Change Materials (Comparison Between Water, Sand, Concrete, Clay and Plaster)

The materials with phase change benefit from the latent heat in addition to significant heat.

In what concerns us here, we are interested in the change of solid-liquid state during the heating and in the change of liquid-solid state during cooling. Our choice is related to organic materials with mixture with intervals of temperature, either paraffin, or fatty acids.

The physical characteristics of paraffin are shown in table 2.

Table 2. Examples of physical properties of paraffin.

	Paraffin			
	Tetradecane	Hexadecane	Octadecane	Eicosane
Formulate	C14H30	C16H34	C18H38	C20H42
Fusion point [°C]	5.5	16.7	28	39.6
Enthalpy of fusion [kJ/kg]	226	237	244	247
Thermal conductivity [W/m. °C]	0.18	0.18	0.25	0.25
Mass heat capacity [kJ/kg. °C]	2.07	2.11	2.16	2.21
Solid density [kg/m ³]	825	835	814	856
Liquid density [kg/m ³]	771	776	774	778
Vapour Pressure [Pa]	133 to 75°C	133 to 105°C	133 to 75°C	133 to 100°C
Surface Tension [N/m]	27.410 ⁻³	3.4	27.410 ⁻³	—
Viscosity [cp]	2.1	—	3.4	—

We can differentiate materials according to their thermal properties, in particular their conductivity, heat capacity, diffusivity and effusivity which playing a major role in the storage of solar heat and its restitution to the coolant water contained in the heat exchanger (tables 1 & 2).

3. Design and Realization of Five Integrated Storage Solar Collectors

We study here an auto-storage type solar water-heater, made up of a flat tank painted in black placed inside a trunk. The unit is closed by a simple or double glazing or a double polycarbonate plate (figure 1).

Figure 1. Diagram of an integrated storage solar water heater.

4. Tests

4.1. Experimental Protocol

The tests were carried out in June 2014, thanks to measuring instruments of precision provided by the National School of Engineering of Gabes, Tunisia. Various climatic parameters were measured such as the ambient temperature, speed of wind, the temperature in the water-heater and the solar flux. The precision of measurements of the temperatures, ensured by digital display panels, is of ± 0.5 C. For solar flux the precision is of $\pm 2\%$.

The study of the solar water heaters is made under real conditions of operation. The solar collector is tilted to 45° and is directed towards the south.

The temperature measurement is made by thermometers with digital display of precision. Measurements begin at 8 am until 6 pm, and at each hour the water temperature is recorded, at the inlet and the outlet of all the solar collectors.

4.2. Tracing of the Curves of Measurement

- a) The curves of the water and ambient temperatures during twenty four hours, for five storage materials: (collectors orientated towards the south, slope of 45°) are given in figure 2.

The temperature measurements are taken hour per hour, for the five waterheaters simultaneously and under the same climatic conditions.

Figure 2. Variation of the water temperature for twenty four hours according to the storage material nature. (Am-T: Ambient temperature; MCP: phase change material).

During diurnal heating, clay and sand heat more, but in night cooling in fact rather and the PCM parks the highest temperature.

The maximum of temperature is reached 1) for PCM with 69°C , 2) for water and concrete with 70°C , 3) for sand with 78°C , and clay with 80°C , under an ambient temperature of 30°C .

The maximum of temperature is reached for 1) clay with 80°C , 2) sand with 78°C , 3) water and concrete with 70°C ,

and PCM with 69°C , under an ambient temperature of 30°C .

Hence, we can note that the ambient temperature has a great effect on the heat losses of the solar collectors during the night, especially under a clear sky.

- b) The water temperature and of the ambient one are recorded during three days for five storage materials: (collectors orientated towards the south, slope of 45°) as depicted in figure 3.

Figure 3. Variation of the storage materials temperatures during three days (5 to 7 June 2013).

According to figure 3, the temperature of the water contained in storage quickly increases during the day, then night cooling slowly lowers the water temperature.

The water of storage has much inertia to heat (high C_p) in the day, and quickly cools in the night because of its strong thermal conductivity with the absorber which cools by radiation towards the sky.

As for storage in sand and the concrete, their thermal inertia and their diffusivity are less significant than those of water, they heat more and their cooling is less significant

because of their strong density.

4.3. Thermal Loss Coefficient Of The Collector And Stored Heat Temperatures Quantity

With the aim of comparing the temperature evolution between materials during the night one can calculate the thermal loss coefficients U ($W/m^2\text{°C}$).

$$\text{With: } U = \frac{\rho \cdot c_p \cdot v}{\Delta t \cdot S} \ln \left(\frac{T_i - T_{amb}}{T_f - T_{amb}} \right)$$

Material	U ($W/m^2\text{°C}^{-1}$)
concrete	9
Sand	5
clay	5
PCM	2.2
Water	3

This loss has an influence on the heat quantity stored in materials.

With: $Q/m = c_p \Delta T + L^*$ L^* : latent heat of PCM = 243 kJ/kg

Figure 4. Night decrease of the stored heat quantity.

Interpretation

By comparison of the thermal loss coefficients of the solar collectors, one retains that the PCM and water have weak losses during night which has a direct influence on their storage heat capacity.

5. Conclusions and Prospects

The water usually used for the heat storage has the handicap to corrode the metal walls, usually made out of steel. Even the most effective treatments do not resist after few years of use. Other studied materials can replace water, such as concrete, clay and even sand. The phase change materials can be promising since they allow more stored heat. Paraffin tested in this present work is part of them. The quantity of heat stored by paraffin is more than the double of that stored in water, and even more for other tested materials.

Nomenclature

A: Useful surface area of the collector m^2
 C: Specific heat of material $J/Kg\ K$
 D: Diffusivity m^2/s
 E: Effusivity $W/m^2K\ s^{1/2}$
 IN: Solar flux W/m^2
 m: masse kg
 S: useful surface area of the collector m^2
 ΔT : increase in temperature K
 Δt : Duration h
 T_a : Ambient temperature K
 V_s : Volume of racking litter
 U: Coefficient of the losses during the night W/m^2K
 V: Speed of wind m/s
 ρ : Density of material Kg/m^3
 α : Absorption coefficient of absorber
 τ : Coefficient of transmission
 η : Efficiency
 C_p : Specific heat of material $J/Kg\ K$
 D: Diffusivity ($10^{-6}\ m^2/s$)
 E: Effusivity ($J/m^2.K.s^{1/2}$)
 U: thermal loss coefficients ($W\ m^{-2}\ K^{-1}$)
 ρ : Density of material Kg/m^3
 λ : thermal conductivity $W\ m^{-1}\ K^{-1}$
