Peng, H., Y. Yu. The Impact of Government R&D Support on SMEs Financial Growth: Evidence from China. *International Journal of Economics, Finance and Management Sciences*. Vol. 1, No. 5, 2013, pp. 205-214. doi: 10.11648/j.ijefm.20130105.11

Abstract: This paper investigates the impact of government R&D support on financial growth of SMEs, and analyzes the significant different supportive effect for the enterprises with different nature of control rights. We take 516 listed companies from the SMEs' board on Shenzhen stock market as sample, using the data from 2006 to 2011 and implementing the method of Propensity Score Matching to relieve the sample selection bias. The empirical results indicate that: On the whole, government R&D support can effectively improve the financial growth of SMEs, and demonstrates an 1-2 year-lagged-effect; the property of enterprises' ultimate controller also has extraordinary impact on R&D supportive effect, financial growth of non-state-holding companies which have accepted R&D support will turn out to be more significant improvement, while that of the state-controlled enterprises have not been significantly enhanced in the short-term, or even fared-worse than the matched samples.

Keywords: Government R&D Support, SMEs, Financial Growth, Propensity Score Matching

1. Introduction

In this article we aim to understand the effectiveness of these government R&D supportive policies by using in-sights from both economic theory and statistic model. SMEs play an increasingly important role in promoting urbanization, creating jobs, increasing tax revenue, enhancing technological innovation and regional economic development and so on. However, SMEs are faced with growth bottlenecks from aspects of management, capital, innovation and so forth; governments have attached great importance to support SMEs, especially for SMEs' R&D activities. In recent years, the Ministry of Finance, Ministry of Science and other central ministries coordinated with local government departments has set up hundreds of SMEs support programs to promote SMEs' R&D in China, including SMEs Technology Innovation Fund, technology incentives and tax concessions and so forth. Prior literatures have studied these policies effectiveness in pro-moting the firm's R&D investment or increasing the company's innovation output, but the research literature from the perspective of corporate financial growth is still uncommon, we attempt to apply Propensity Score Matching method to test the validity of the government

R&D supportive policies. Can the policies significantly improve SMEs financial growth; will the ownership properties cast a significant difference on the policy validity? By doing so, our concerns may help the government construct a wide range of more effective policies for SMEs' R&D activities, and also promote SMEs to take the R&D incentives seriously to increase R&D investment, improve product technological content and cultivate better-established brands.

Compared with the relevant literature, the innovation lies in this article as follow: (1) Enriching the relevant literature by testing the effectiveness of government R&D support policies from the financial growth perspective; (2) Using 516 micro-enterprises financial data from 2006 to 2011 on the background of Chinese market to implement empirical analysis, it is still so far the largest number of observations within the similar studies, a larger sample of data probably can effectively improve the credibility of research conclusions; (3) Alleviating concerns about the endogeneity problem which might be caused by sample selection bias, that is the government may be more inclined to choose the blue-chip companies when allocating the R&D supportive resources, we implement the propensity score matching method (hereinafter referred to as "PSM"), thus we reconcile the biased problems that probably occurred in

traditional parametric tests and improve the credibility and robustness of research implications; (4) In order to test the ownership propriety effect on the support policies, we further discuss the relationship between the financial growth performance and the support policies among the SMEs with different types of controlling ownership.

The rest of the paper is organized as follows: Section 2 discusses the drafting of the issues and the related literature; Section 3 shows the research design and elaborates on the concept of the PSM that is used for the empirical analysis; Section 4 presents the empirical results; and Section 5 closes with a summary of the main results.

2. Literature Review

The issue on the government support validity has been much concern for scholars, there is a bulk of archival literatures in the area. SMEs are confronted with obstacles from many aspects. On one hand the SMEs hold smaller operational size, lower management level, relatively higher tax burden, which is leading to lack of internal capital accumulation, while external financing channels for SMEs are also narrower (Lerner, 2002^[27]); On the other hand, because of the technology and knowledge spillovers effect, R&D activities will inevitably encounter market failure and underinvestment problem (Arrow, 1962^[1]; Tasse, 2004^[38]). To this end, scholars agree that it is necessary for the government to provide subsidies and tax concessions and other preferential in order to support R&D activities. Although the government-supported R&D activities can enhance innovation capability, these supportive validity may also be greatly reduced due to government rent-seekers during the implementation (Klette *et al.* 2000^[26]), the effectiveness of the government supportive policies should be a more important issue, relevant departments need to pay more attention to and evaluate the specific implementation validity of the government R&D support for SMEs (Corley, 2007^[7]), or else the funds that are designed to enhance the ability of the private sector R&D will have been wasted (Hsu *et al.* 2009^[21]).

Theoretical framework and systematical research methods on evaluating the effectiveness of SMEs supportive policies are not yet perfect, meanwhile, coupled with difficulties in collecting data and distinguishing external interference factors, the prior relevant studies are still not in full swing, and mainly carried out from the point of corporate R&D investment (Wallsten, 2000^[39]), new product output (Li *et al.* 2012^[29]), patents output (Colombo, 2009^[8]). After the newly-developed product being put on the market, the financial performance of the enterprise is bound to make reaction, to the best of our knowledge, the relevant study from a financial perspective specifically considering effects of government R&D support is still rare. Many indicators to evaluate and measure business growth performance, such as business revenue growth, number of employees growth, profits growth, market share growth, etc. (Boardman *et al.* 1981^[3]; Konings, 1997^[23]; 2002^[25]; Grilli

et al. 2009^[8]; Hsu *et al.* 2009^[21]).

Financial growth is affected by many factors, innovation capability of enterprise plays an important role in its growth (Penrose, 1959^[32]); firm size, the quality of managers and corporate business strategies are also crucial factors for SMEs financial growth. Additionally, the business life cycle, size or ownership propriety, external financing constraints, the legal system and other factors also affect the financial growth of enterprises (Storey, 1994^[36]; Becchetti *et al.* 2002^[4]; Alecke *et al.* 2011^[2]). Only effectively control these factors that might influence corporate financial growth performance can we evaluate the effectiveness of the support.

Former scholars hold quite different opinions on the empirical results. Some scholars believe that the government's R&D for SMEs support policies to be effective. Hsu *et al.* (2009^[21]) employs the nine years of data from 110 Taiwan government support projects and concludes that technology productivity of enterprises that get government support is significantly better than that are not supported; Czarnitzki (2011^[10]) finds that R&D tax credit significantly promote the company's innovative product yields using a sample of manufacturing firms from Canada. Foreman-Peck (2012^[16]) argues that the UK government-supported SMEs' innovation performances significantly are higher than the samples without support. Grilli *et al.* (2012^[20]) holds that high-tech company's sales revenue and employee growth rate are significantly higher than other similar enterprises, using the data from EU member countries. For Chinese scholars (Zhu *et al.* 2003^[42]; Xiao *et al.* 2007^[40]; Yuan *et al.* 2012^[41]) also believe that the government supportive policies play an important role in the process of SMEs technological innovation. However, some scholars are not optimistic about the effectiveness of the government R&D support programs. Goolsbee *et al.* (1998^[17]) argues that the R&D funds that government's support for private sector do increase researchers wage levels but still supplant the private sector's innovation output; Wallsten (2000^[39]) finds that the U.S. corporate tax incentives for SMEs have extruding effect on R&D yields; Marcus and Howard (2003^[30]) do not find evidence that selective R&D subsidies activity will have a significant impact on innovation productivity from the background of the Japan and South Korea's industrial policies implementation; there is serious dislocation between the expectation of government support policies and the actual effect (Chen *et al.* 2005^[11]; Gu *et al.* 2006^[19]).

The main difficulty in evaluating the effectiveness of government R&D support lies in the non-random selection when choosing the support object and result in the endogeneity problem, even if the final conclusion that financial growth of supported enterprise is significantly higher than that is unsupported, we still cannot argue that the better growth performance stems from government R&D support, it is likely that only those high-growth companies can benefit from government support policies. Thus, the estimated results according to the traditional

method of parameter estimation will be biased, which is widely concerned in the extant literature. Multi-stage regression is widely accepted to decrease this type of endogeneity problem, but there is a big difficulty in instrumental variables selection. As PSM developed in recent years, some studies begin to take its advantage to deal with such selection-bias problem (Rubin *et al.* 1977^[33]; Herrera *et al.* 2010^[22]; Czarnitzki, 2011^[10]; Giovanni Cerulli, 2012^[12]).

In summary, our results help reconcile the inconsistent prior findings concerning government R&D support policies. We aim to extend the related researches from the point of financial growth performance by adopting the increasingly sophisticated approach PSM. This paper also considers the externality and government intervention (Arrow, 1962^[1]; Lerner, 2002^[27]) and it provides additional evidence on the effects of corporate ownership propriety on the financial performance (Kole *et al.* 1997^[22]; Boubakri *et al.* 2005^[5]).

3. Research Design

3.1. Data and Sample Selection

This article combines financial data from Wind, CSMAR and RESSET; the data regarding government support for SMEs' R&D is manually retrieved from the annual reports. Taken the fact that there might be some sample database mistakes and errors in statistical; we make the following selection of the sample data: (1) Excluding the observations with missing data records of the variable, such as net assets per share growth rate, total asset turnover ratio, total revenue growth rate, operating profit growth rate, growth rate of net assets, total assets growth rate; (2) Excluding the samples whose asset-liability ratio is more than 1, that is insolvent enterprises; (3) Excluding the observations where the total asset growth exceeding 150%, in order to eliminate the interference arising from mergers and acquisitions; (4) Excluding the company data of listed year, in order to reduce shocks arising from the possible earnings management due to listing; (5) Excluding companies in finance and ST/PT classes. Besides, we winsorize the main variables (excluding dummy variables) on the level of 1% and 99%, in order to mitigate the interference of the outliers.

We split sample enterprises into two categories (non-state-holding enterprises and state-controlled enterprises) according to the nature of ultimate control ownership rights. Seen from Table 1, the numbers of state-controlled and non-state-holding enterprises are both increasing year by year, but the proportion of state holding enterprises is declining, accounting for a minimum of 17.84% and a maximum of 30.53%, indicating that Chinese government has paid attention to the economy privatization. 516 small board listed companies range from a total of 12 industries¹,

75 % of enterprises are in the manufacturing sector, the information industry accounts for about 10%, all other industries make up no more than 5%.

Table 1. 2006-2011 Sample Enterprises Distribution

Panel A: By Year	Non-State dComp	Prop(%)	Stated Comp	Prop(%)	Totally
2006	35	76.09	11	23.91	46
2007	66	69.47	29	30.53	95
2008	135	71.81	53	28.19	188

3.2. The Basic Idea for PSM

It's impossible for the given SEM to be supported and unsupported in the same period; therefore, comparing the growth differences between the two states is generally not feasible, like doing experiments research, only one state can be observed, while the other is counterfactual. In order to solve this problem caused by the unobserved performance, Rubin *et al.* (1977^[33]) propose matching method, the basic idea is that if you can find a control group that is as similar as possible to the supported, it would be sufficiently reduce sample selection bias, when evaluating the effectiveness of the policies. However, judging from one particular feature (such as size) often cannot be sufficient to achieve the satisfied matching effect in the process of matching the control group. Therefore, PSM method condenses a plurality of characteristic factors into one single indicator, the propensity score values (referred to as PS values), enables multi-dimensionality reduction matching. Rosenbaum & Rubin (1983^[34]) estimate the Logistic model to obtain the probability ($p(X_i)$) that can receive government R&D support and to match the treated and controlled groups.

$$p(X_i) = \Pr[D_i=1 | X_i] = E[D_i | X_i] \quad (1)$$

Where X_i is the vector of characteristics variables that count on receiving the support policies or not, D_i is the

1 Classified by the Chinese SFC Industry Classification Standard

indicator variable (=1, be supported; =0, otherwise). ATT (Average effect of treatment on the treated) is the key indicator that can test the different performance of the supported and control group (Becker and Ichino, 2002^[6]),

$$\begin{aligned} \text{ATT} &= E[Y_{1i} - Y_{0i} | D_i = 1] \\ &= E\{E[Y_{1i} - Y_{0i} | D_i = 1, p(X_i)]\} \\ &= E\{E[Y_{1i} | D_i = 1, p(X_i)] - E[Y_{0i} | D_i = 0, p(X_i)] | D_i = 1\} \end{aligned} \quad (2)$$

Where Y_{1i} and Y_{0i} represent the performance of supported and controlled groups respectively.

3.3. Matching Methods

We cannot estimate the ATT of interest by directly using (2) even though the propensity scores have been estimated. The reason is that $p(X_i)$ is a continuous variable, and thus it is impossible to find two units with identical propensity score (Lian *et al.* 2011^[28]). The most widely used matching methods are Nearest-Neighbor Matching, Radius Matching and Kernel Matching.

The nearest neighbor matching method is to look both forward and backward for the j^{th} sample from the control group to match the supported samples by judging the PS values estimated by the probability model. Let p_i^S and p_j^C represent the estimated propensity score value of the supported and controlled group, respectively. Then, the nearest neighbor j can be described as follows,

$$C(j) = \min \|p_i^T - p_j^S\| \quad (3)$$

Similarly, the radius matching method is to search all samples in the control group, and whose PS falls within a radius r from p_i^T are matched to the supported sample i . The matching principle is as,

$$C(j) = \{ \|p_i^T - p_j^S\| < r \} \quad (4)$$

We can calculate ATT if the matched samples are identified according to Becker and Ichino (2002^[6]).

3.4. Variables Definition

The propensity score on SMEs' access to achieve government R&D support are required to estimate prior to implement PSM non-parametric test. In this paper, we adopt the Logistic probability model to calculate propensity scores consistent with (Dehejia and Wahba, 2002^[14]). Business performance, R&D expenditures, asset size, number of employees, the listed age, industry characteristics (Czarnitzki, 2006^[9]; 2011^[10]; Giovanni Cerulli, 2012^[12]) and other characteristic variables are all the key factors that affect the probability to obtain government support. According to the existing theoretical and empirical research findings, the characteristic variables selected are shown in Table 2.

4. Empirical Results

4.1. Descriptive Statistics

Seen from Table 3, in addition to employees, Tobin's q is of two and three missing values, respectively, other variables are all of no missing observation holding number of 1409. The standard deviation of characteristic variables is less than 3.5, except for net asset per share growth rate, size, number of employees and other variables, indicating that these characteristic variables fluctuate slightly, the difference between the mean and the median is also not large, and we can approximately assume these variables are normally distributed. Total operating income growth rate and other variables that reflect the SMEs' financial growth hold large variances, suggesting the mean and median are significantly differently, it's usually considered that these variables do not obey symmetrical distribution, so these variables are not put into the Logistic model to calculating propensity scores, but the fact that asymmetrical distribution and greater volatility does not affect the estimates of ATT after matching.

Table 2. Variables Definition

Name	Symbol	Definition
Size	lna	natural logarithm of the total assets
Employees	lnemp	natural logarithm of the employees
Listed age	lnage	natural logarithm of months from the listed date
R&D expenditure	lnrdex	natural logarithm of the R&D expenditure
Adjusted profits	adprofit	cash flow from operational activities/ total assets
Ownership	shrcr3	top three largest shareholder's ownership
Net assets per share growth rate	ncapsg	(net assets per share at end of t-net assets per share at the end of t-1)/ net assets per share at the end of t-1
Total assets turnover	rat	net operational income/average total assets
Return on total assets	roa	net profits /average total assets
Return on equity	roe	net profits /average equity
Market-to-book of equity	tobinq	market value of equity/book value of equity
Industry	Industry	11 industry dummy variables

4.2. Logistic Regression Model

We employ Logistic regression model to calculate the propensity score, *i.e.* the probability that the samples can obtain government R&D support, and government may examine the past condition of candidates when it allocates the supportive resources. Therefore, in this paper we select one-and-two lagged characteristic variables to estimate Logistic regression model, as described in equation (5),

$$p(X_i) = \Pr[\text{supp}_i | X_{t-1}] = \exp(\beta X_{t-1}) / (1 + \exp(\beta X_{t-1})) \quad (5)$$

Where supp_i indicates whether a company receives government R&D support in t year (=1, supported; =0, otherwise); X_{t-1} (or X_{t-2}) represents the vector of characteristic variables in $t-1$ (or $t-2$) year, β indicates the regression coefficients for characteristic variables.

We present the regression results of Logistic model in Table 4, both Pseudo- R^2 and AUC (Stein *et al.* 2005^[37], Okeh, 2012^[31]) are considered to evaluate the goodness of fit of the model. Judging from the model that employs one-year-backward or two-year-backward characteristic variables, we could see the coefficients of asset size is significantly negative ($p < 0.01$), indicating that the smaller enterprises are more likely to be supported in China, which is opposite to the conclusions from Herrera *et al.* (2010^[22]) and Dirk Czarnitzki (2011^[10]). That's probably for the reason that the R&D support budget from Chinese government is still not high, compared with smaller SMEs, the larger-scale ones might operate in relatively better condition and keep stronger capital and technology strength and higher motivation to R&D activities, policy-makers are more inclined to support the enterprises with smaller asset size; this may also be due to the smaller companies faced with greater financial constraints, technical development bottlenecks, and have more incentives to apply for R&D support.

Table 3. Variables Descriptive Statistics

Variables	Symbol	N	Mean	S.D	Min	Med	Max
Dummy	supp	1409	0.47	0.50	0.00	0.00	1.00
Size	lna	1409	7.29	0.79	5.82	7.21	9.68
Employee	lnemp	1407	7.31	0.88	5.37	7.29	9.41
Listed age	lnage	1409	3.24	0.62	2.49	3.18	4.43
R&D expenditure	lnrdex	1409	5.95	3.36	0.00	7.38	9.84
Adjusted profit	adprofit	1409	1.21	2.86	-7.06	0.62	46.24
Ownership	shrcr3	1409	0.54	0.13	0.23	0.55	0.84
Net assets per share growth rate	ncapsg	1409	-5.59	27.44	-73.84	0.00	143.20
Total assets turnover	rta	1409	0.79	0.46	0.18	0.68	2.76
Return on total assets	roa	1409	0.06	0.05	-0.08	0.06	0.24
Return on equity	roe	1409	0.10	0.07	-0.16	0.09	0.31
Maket-to-book of equity	tobinq	1406	3.17	1.94	1.07	2.59	11.30
Total operating income	oprgr	1409	23.37	26.55	-32.70	20.54	110.20
growth rate							
Operating profit growth rate	oprogr	1409	23.94	168.30	-666.30	14.44	1134.00
Net assets growth rate	ncagr	1409	16.37	28.43	-15.63	7.49	155.50
Total assets growth rate	tag	1409	20.05	22.37	-15.86	14.24	104.00

The impact from corporate employees size is insignificant; Newly listed SMEs have more access to get favorable government support policies; the coefficient of

R&D expenditures in Panel A regression 2 is significant positive at 10% level, but the coefficients are not significant in the other regressions; what's more, we can be sure that government R&D support is positively correlated with corporate past financial performance, adjusted profits can significantly increase the probability of obtaining government support, when taking return on total assets and return on net assets as proxies, although coefficients are not significant in Panel A, the two-year-backward coefficients of these variables are significantly positive ($p < 0.01$), which gives evidence that Chinese government pays more attention to the profitability of enterprises. This may be because enterprises with better earnings can bring more tax revenue to the government; one-year-backward shareholders' ownership shows no significant effect on getting the support, but more concentrated two-year-backward ownership would reduce the likelihood of getting government support. In all models, the coefficients of Tobin's q are significantly negative ($p < 0.01$), suggesting that the enterprises with higher market value are less likely to obtain support, it is possible that for the listed company, the higher market value of the enterprise, the easier to be financed by the market, the relatively weaker financial constraints.

4.3. Samples Matching Results

We take both lagged one- and two-year characteristic variables into consideration when calculating the kernel density; and the density of PS value before and after samples matching from supported and controlled groups is presented in Figure 1.

Figure 1. The Kernel Density Function Curves of Propensity Score

Compared with the first two matched groups, there is no denying that their density function curves of PS values are different, which suggests the controlled samples might

involve certain degree of inappropriate information, and lead to a big different distribution to the supported samples. If no effective method is taken into consideration, the statistical inference judged from direct comparison of these two sets of samples data would be necessarily biased. After matching, the kernel density distribution of the two samples becomes more similar, which means, to some extent, the similarity of their PS values has been improved, especially for the case of the two-year-backward model. Results generated by using radius and kernel matching are similar, not repeat them herein.

4.4. Analysis of Average Treatment Effect

To improve the robustness of the conclusions, we employ the three aforementioned matching methods in estimating the sample average treatment effect, the test results are shown in Table 5 Panel A, B and C, respectively. It probable that there is time lag effect for the government support policies, thus, we implement one- and two-year government support variables in propensity score matching model.

According to post-matching results from total samples, in the case of lagged-one-period, total revenue growth rate (oprgr) of the supported samples, on average, is of 1-3 percentage points higher than that of controlled group, but not significant; for the case of lagged-two-period case, it's of significant higher 7-9 percentage points for the supported. For the operating profit growth rate (oprog), there is a average-higher 35-43 percentage points for the supported group in the lagged-one-period case, but in the lagged-two-period case, the difference between the two turns to the reversed direction, *i.e.* the supported samples hold a lower operating profit growth rate, on average, than the controlled (unsupported) ones, that's probably because that the companies will do large-scale R&D investment during 1-2 years from receiving the support, result in a lower operating profit growth rate. When using the nearest neighbor matching method, ATT of net assets growth rate (ncag), is negative at the level of 1%, and not significant in the other two methods; the total assets growth rate (tag) between the two groups is of no significant difference after receiving the support one-year later, but after two years from obtaining government support, the total assets growth rate will be higher than that of controlled group by 3-4 percentage points.

Firms with government intervention and control rights are not conducive to maximize shareholder value and associated with high rents seeking, agency costs. To further analyze the effect of final ownership control rights on the effectiveness of government R&D support, all samples are classified into two categories by their ultimately controlled rights, *i.e.* state-controlled enterprises and non-state-holding enterprises. Seen from the lower parts of Table 5, for non-state-holding enterprises, total operating revenue growth rate difference between the supported and controlled groups is not significant after obtaining the support one year, but after being supported two years, the

supported group's growth rate is significantly higher by about 10 percentage points. One-period-lagged operating profit growth rate between the two groups is significantly and positively different, while the case for two-period-lagged is not significant, indicating that the supported companies continue to increase R&D investment and lower the operating profit growth rate. The net assets growth rate of supported group is not significantly higher than that of the controlled after being supported one year, or even on average fared-worse than the control group, but after obtaining government support two years later, it's significantly higher for the supported, which demonstrates the effectiveness of the policies. When it comes to total assets growth rate, the situation is similar to net asset growth rate, once again suggests that government supportive policies behave time lag effect.

For state-owned holding companies, in the nearest neighbor and kernel matching approach, we find the counter-intuitive fact that total revenue growth rate from the supported samples is, on average, significantly lower than that of the control enterprises after one year being supported, besides, whether the support lagged one or two period, for total profit and net asset growth rate, the average treatment effect (ATT) differences between the two groups are not significant, which is probably attributed to state-controlled enterprises are usually of larger assets, located in high-end manufacturing, higher industry risk level, longer product development cycle and relatively larger investment scale. Therefore, the government support still cannot significantly improve their financial growth in the relatively short period.

5. Conclusions

The paper examines the impact of government R&D support on the financial growth of SMEs. On the base of investigating the characteristics of SMEs that might affect their access to the support, we employ propensity score matching (PSM) to undermine the sample selection bias. The empirical results lead to two important implications, (1) The younger and smaller companies are more likely to get government R&D support, and larger-scale of past R&D investment can significantly increase the probability of their access to government support; what's more, corporate earnings performances act as key factors in obtaining R&D support, the higher adjusted profits level, the return on total assets or net assets, the bigger chance to acquire the support; In contrast, the higher market value of SMEs, the less likely to be supported. (2) Judging from the total sample enterprises, the government R&D support policies play significant and positive role in promoting the financial growth of SMEs, but validity of these supportive policies manifests at least one-year-lagged effect; the paper also shed light on the effect of ultimate control rights in the process of implementing these incentive policies, financial performance of the non-state-controlled enterprises is more ideal, while the state-holding enterprises still make no big

difference in terms of financial growth during 1-2 years from being supported, which gives evidence that the government controlled SMEs are of low economic efficiency, neglecting their unique characteristics.
