Abstract: *Amaranthus hybridus* L. is an important vegetable in Nigeria, grown mainly for its highly nutritious leaves. In a bid to explore the possibility of increasing the infra-specific diversity of the crop, we induced three accessions of *A. hybridus* from Anambra State, Nigeria with x-ray particles using various concentration levels. The experimental layout composed a 5 x 3 x 3 Randomized Complete Block Design arrangement, with treatment levels: 1 MGY, 2 MGY, 4 MGY, and 6 MGY, selectively allotted to the different accession based on a preliminary dosimetry test. Morphological data were recorded and subsequently leaves samples subjected to Deoxyribonucleic Acid (DNA) extraction and Random Amplified Polymorphic DNA (RAPD) analysis. The results show that except for inflorescence weight, other morphological data were not statistically significant. However, RAPD techniques identify some variations induced by x-ray particles on the different accessions. Ogbunike accession irradiated with 4 MGY appears to show the optimum concentration of x-ray particles required to induce genetic variability in *A. hybridus*. These findings are of paramount importance to plant breeders, whose primary tool is to identify variations to produce better yielding varieties.

Keywords: X-Ray, *Amaranthus hybridus* L., Genetic Variability, Mutation, Diversity, RAPD

1. Introduction

Genetic variation is advantageous to a population because it enables some individuals to adapt to the environment at the same time, ensuring population survival in the ever changing environmental condition [1-2]. From an anthropocentric perspective, such genetic variability offers variable traits for breeding selection and plant genetic resources improvement [3]. Genetic variability in plants is caused by various factors, such as: mutation (which can create entirely new alleles in a

population), random mating, random fertilization, and recombination between homologous chromosomes during meiosis (which reshuffles alleles within an organism's offspring). Mutations can have significant effects on the individual when they occur in somatic tissue, but are only inherited if they occur in germ-line tissue. Mutations in germ-line tissue are of enormous biological importance because they provide the raw material from which natural

selection produces evolutionary change [4]. More often, these genetic changes are induced by mutagenic agents such as x-rays, gamma rays, beta rays, neutrons, chemicals, high temperature and low pH [5]. Plants sometimes transmit somatic mutations to their descendants asexually or sexually (in case when flower buds developments in somatically mutated part of plant). Mutations create variations in the gene pool, and the less favorable (or deleterious) mutations are removed from the gene pool by natural selection, while more favorable (beneficial or advantageous) ones tend to accumulate, resulting in evolutionary change [6]. Irradiation has been successfully used for mutation breeding in various crops and ornamental plants [37] and has proven an adept means of encouraging the expression of recessive genes and producing new genetic variations [23, 36-38]. A study [22] reported that the height of *Zea mays* coleoptiles exposed to X-ray doses up to 500 r was not affected and shoots of the plants which received over 800 r showed the effects of irradiation by delay in bursting through the coleoptiles and failure to reach the height attained by their controls during the time of the experiment. The starch and sugar content of Sweet Potato has been improved by mutation breeding [39]. A study [34] mutated *Amaranthus caudatus* L. with Gamma rays and successfully obtained semi-dwarf and dwarf stature, non-branching pattern, improved protein content and pigment mutations (colour of plants and grains). Taxonomically, these mutations which cause change in the plant phylogeny can lead to the formation of new plant varieties, which needs to be examined and identified appropriately.

The genus *Amaranthus*, with about 70 species, is characterized by a high degree of morphological diversity and a wide spectrum of adaptability to different ecological conditions [7]. All amaranths are drought resistant C₄ photosynthetic plant that can grow well in saline, alkaline, acidic or poor soil. This genus, which originated in the New World, is an ancient crop that was already under cultivation 5000-7000 years ago [8]. The amaranth gene pool involves a diverse group of wild relatives and weedy species, and individual Landrace populations [7]. Recently, amaranth has been described as one of the new world super grains and is gaining popularity among health-conscious consumers in many countries of the world, including the United State and Japan [8]. It has been identified as a very promising food crop because of its exceptional nutritive value as judged by its protein and lipid content, as well as for its essential amino acid composition that has relatively high lysine content [9]. In addition, amaranths are also good sources of minerals and vitamins and they contain nutrient than most of the common cereals and legumes [10]. Cultivated amaranths are used for food grain, medicine, leafy vegetables, forage, ornamental gardening, and other potential uses [11-12]. Amaranths as C₄ plants, can contribute to mitigate CO₂ concentration, the major provoking greenhouse effects. Because of high biomass production and ability to accumulate heavy metals,

they can be used as a renewable energy source and for phytoremediation [13]. It is also used in gluten free diet [14]. Amaranth belongs to the group of plants which genetics are poorly studied [15-19]. Such situation is explained by a complexity of its hybridization, caused by an extremely small size of its reproductive organs and a special constitution of its inflorescence [20]. A careful assessment of available literature has revealed that there is a scarcity of information on the irradiation of *Amaranthus* spp. especially with X-ray. Application of RAPD analyses widely used in various plant species will allow by passing these difficulties and assist in the investigation of amaranth evolution, taxonomy and genetics. Considering the diverse utility base of this promising plant, we hypothesized that an induce variation in the genome of some naturalized population might result in even greater prospects and adaptability in the face of climate change and human-induced environmental impact. Therefore, the present study was undertaken to investigate the mutagenic effects of different x-ray doses on *Amaranthus hybridus* L. accessions

2. Materials and Methods

The experiment was conducted in an experimental farm behind the Mushroom House, College of Natural Sciences, Michael Okpara University of Agriculture, Umudike. Umudike is located approximately at latitude 05° 29' 1" N, longitudes 07° 32' 1" E. Umudike falls within the rainforest zone of southern Nigeria, with a mean altitude of 123 meters. Daily mean temperature ranges from 23°C and 32°C. The field work was carried out between the months of July to September, 2015. The seeds of the *Amaranthus* accessions used were obtained from various localities (Ezi Ogidi, Ogbunike and Oye Olisa) in Anambra State in June 2015. Samples of the germinated accessions of *Amaranthus hybridus* L. were properly identified at the Department of Botany herbarium, University of Nigeria, Nsukka.

Table 1. Accessions of Amaranthus hybridus and collection points.

S/n	Accessions	Collection points (GPS location)
1	Ezi Ogidi	6°12'45.68" N 7°04'19 E
2	Ogbunike	6°09'60.00" N 7°03'00 E
3	Oye Olisa	6°13'60.00" N 7°03'11 E

The accessions were treated with radiations at the Radiology Department of the Federal Medical Centre, Umuahia for treatment. Each accession was divided into six parts to include five treatments and one control. The treatments are 1 MGY, 4 MGY, 5 MGY, and 6 MGY. The accessions were planted and a morphological datum (plant height) was taken weekly for one month [34]. The dosimetry was taken from two points on the graph where the plants did best [32-33].

Figure 1. Graphical representation of the dosimetry.

From the graph, it could be deduced that Ezi-Ogidi accession progressed at 5 MGY and 6 MGY while Ogbunike accession did best at 1 MGY and 4 MGY. Finally, Oye-Olisa accession progressed at 5 MGY and 6 MGY.

3. Experimental Set Up

A 5 x 3 arrangement was used in a randomized complete block design (RCBD). The factors were X-Ray levels (MGY) with *Amaranthus* accessions. Each accession was divided into three parts to include two treatments and one control respectively. Ezi Ogidi accession was treated with 5 MGY and 6 MGY, Ogbunike accession was treated with 1 MGY and 4 MGY while Oye Olisa accession was treated with 5 MGY and 6 MGY. Each treatment including the control (0 MGY) was replicated four times. Morphological data collected include plant height, number of leaves, leaf area and inflorescence weight.

4. Data Analysis

One way analysis of variance was used to test the significance of the treatment and subsequent means compared using Turkey HSD (Highest significant difference).

5. DNA Extraction

The DNA of the plant *Amaranthus* was isolated from the young leaf using the traditional CTAB (Cetyltrimethylammoniumbromide) protocols/ method [35]. Lysing stage: *Amaranthus* leaf was cut with a scalpel, ground in a mortar and introduced into 600 µl of extraction buffer and it was incubated at 65°C for 20 minutes. The sample was removed from the incubator and allowed to cool to room temperature and Chloroform was added. The sample was mixed by gentle inversion of the tube several times. Harvest stage: The sample was spun at 14,000 rpm for 15 minutes and the supernatant (5 g) was transferred into a new eppendorf tube and equal volume of cold Isopropanol was added to precipitate the DNA. The sample was kept in the freezer for 1 hour and later spun at 14,000 rpm for 10 minutes and the supernatant was discarded and the pellet was

washed with 70% ethanol later the sample was air dried for 30 minutes on the bench. The pellet was re-suspended in 100 µl of sterile distilled water. DNA concentration of all the samples was measured on spectrophotometer at 260 nm and 280 nm and the genomic purity were determined. The genomic purity ranged from 1.8 – 2.0 for all the DNA samples. The quality of DNA was detected by agarose gel electrophoresis and the size of fragment obtained was about 25 kb for all the samples. The DNA was used in PCR amplification using RAPD markers.

6. PCR Amplification and DNA Electrophoresis

About 10 µl of each DNA was taken into eppendorf tube and 990 µl of sterile distilled water was added to make 1000 µl. The final concentration became 20-50 ng/µl. The reaction mix was carried out in 20 µl final volume containing 60 ng – 80 ng DNA, 0.1 µM of the primers, 2 mM MgCl₂, 125 µM of each dNTP and 1 unit of Taq DNA polymerase. The thermocycler profiles has an initial denaturation temperature of 3 minutes at 94°C, followed by 45 cycles of denaturation temperature of 94°C for 20 seconds, annealing temperature of 37°C for 40 seconds and primer extension temperature of 72°C for 40 seconds, followed by final extension temperature at 72°C for 5 minutes

Agarose gel electrophoresis was used to determine the quality and integrity of the DNA by size fractionation on 1.0% agarose gels. Agarose gels were prepared by dissolving and boiling 1.0 g agarose in 100 ml 0.5 X TBE buffer solutions. The gels were allowed to cool down to about 45°C and 10 µl of 5 mg/ml ethidium bromide was added, mixed together before pouring it into an electrophoresis chamber set with the combs inserted. After the gel has solidified, 3 µl of the DNA, 5 µl of sterile distilled water and 2 µl of 6 X loading dye was mixed together and loaded in the well created. Electrophoresis was done at 80 V for 2 hours. The integrity of the DNA was visualized and photographed on UV light source.

7. Results

The effect of different doses of x-ray irradiation on the morphological characters of the three accessions of *Amaranthus hybridus* L. is depicted in table 3 below. Generally, Ezi Ogidi and Oye Olisa accessions were best induced at 5 MGY and 6 MGY concentrations, however, Ogbunike accessions were best induced at 1 MGY concentration. An evaluation of the Oye Olisa accession reveals that the mean plant height of control was (65.1 ± 9.4)

cm while those recorded in 5 MGY and 6 MGY x-ray irradiation doses decreased from (60.3 ± 9.1) cm to (56.6 ± 7.7) cm respectively. Leaf area was also highest (15.1 ± 1.4) cm² in the accession used as control, followed by 5 MGY irradiated plant (14.5 ± 1.4) cm² and lowest (12.3 ± 1.3) cm² in the 6 MGY x-ray irradiated plant. A similar trend was also noticed when leaf number of the accession was measured, 17.1 ± 1.1 mean size was recorded in the control, while 16.7 ± 1.1 and 16.7 ± 1.2 were obtained in the *Amaranthus* accession irradiated at 5 MGY and 6 MGY respectively. The x-ray radiation had a statistical significant on the fresh and dry inflorescence weight of Ezi Ogidi accessions. Under no irradiation (control), fresh and dry inflorescence weights were recorded at 36.43 g and 6.80 g respectively. The highest fresh and dry inflorescence weight was recorded in 6 MGY irradiated accession as 44.9 g and 11.6 g respectively. 5MGY irradiated accession was lower at 31.8 g and 6.3 g for fresh and dry flower weight respectively versa.

The results of the morphological effect of x- ray irradiated *Amaranthus* (Ogbunike accession) showed inverse response as the mutagen levels increases. The no irradiated accession (control) produced the lowest mean height (54.9 ± 7.7) cm, followed by the same accession irradiated at 1 MGY (57.5 ± 7.6) cm, treatment 4 MGY resulted in the highest plant height value of (67.2 ± 8.06) cm. Leaf area was high (14.2 ± 0.1) cm² in the accession without irradiation (control), but reduced at x-ray irradiation of 1 MGY (14.2 ± 0.2) cm² but was stimulated to (16.1 ± 0.5) cm² with increased irradiation up to 4 MGY. Control produced the highest number of leaves at 16.7 ± 1.01 followed by 4MGY irradiated accession (16.4 ± 1.0) while (16.6 ± 0.98) number of leaves were produced by the accession irradiated 1MGY. However, the above morphological parameters of accession-Ogbunike were not

statistically significant at $p=0.05$. The x-ray radiation had a statistical significant on the fresh and dry inflorescence weight of Ogbunike accession. The average fresh and dry inflorescence weight for the Ogbunike accession as recorded for control gave the highest (44.01 and 10.9) g respectively. 4 MGY irradiated accession gave fresh and dry flower weight of (32.88 and 9.4) g respectively. While fresh and dry flower weight of Ogbunike of 1 MGY x-ray irradiated accession was apparently low at (32.12 and 7.2) g respectively.

The results of the effect of x-ray on *Amaranthus* (Oye Olisa) accession shows 5 MGY x-ray irradiated accessions had the highest height of (67.5 ± 9.2) cm, followed by the control (66.8 ± 8.4) cm, but the accession that received 6 MGY x-ray irradiation showed the lowest mean height of (54.9 ± 8.1) cm. Leaf area of no-irradiation (control) of this accession was low at (13.0 ± 1.4) cm², but stimulated by 5MGY level of irradiation at (14.1 ± 1.4) cm² and also decreased to (13.5 ± 1.3) cm² at the irradiation of 6MGY. On the other hand, control gave the highest number of leaf (17.2 ± 1.1) , followed by the accession irradiated at 5 MGY (16.9 ± 1.03) , but slightly decreased to 16.8 ± 1.2 at x-ray irradiation of 6 MGY. However, the above morphological parameters of accession-Oye Olisa were not statistically significant at $p=0.05$. The fresh and dry inflorescence weight of the Oye Olisa accession with treatment 5 MGY irradiated *Amaranthus* accession produced the highest (65.19 g) fresh weight, but second in dry weight (13.49 g). Accession with no irradiation produced highest fresh inflorescence weight of 61.8 g and highest dry flower weight value of 16.4g. X-ray irradiation at 6 MGY had the lowest weight of 36.81 g and 7.47 g for fresh inflorescence and dry flower weight respectively.

Table 3. Treatment means and standard error of growth parameters for the different accessions.

Morphological characters	Ezi Ogidi			Ogbunike			Olisa		
	control	5 MGY	6 MGY	control	1 MGY	4 MGY	control	5 MGY	6 MGY
Plant height	65.5 ^a ±9.4 ^a	60.3 ^a ±9.2	56.6 ^a ±8.06	54.9 ^a ±7.7	57.5 ^a ±7.6	67.2 ^a ±8.6	66.8±8.4 ^a	67.5 ^a ±9.2	54.6 ^a ±8.1
Leaf area	15.1 ^a ±1.4	14.5 ^a ±1.4	12.3 ^a ±1.3	15.3 ^a ±3.1	14.2 ^a ±0.2	16.1 ^a ±0.5	13.6 ^a ±1.4	14.5 ^a ±1.4	13.5 ^a ±1.3

HSD = 95%, similar superscript, a = shows no Significant Difference, different superscript shows significant difference.

The scoring of bands was carried out to mark genetic differences among the various accessions. The electrophoretic banding pattern presented in below (table 4) shows that Ezi Ogidi accession irradiated at 5 MGY indicates a genetic banding at locus-4 with no irradiation (control) accession, at 6 MGY, bands were visible at loci -1 and -5, however, at but bands at -2, -3, and -6 loci with 5 MGY accession. Ogbunike accession shows a completely different banding pattern with the control indicating that mutation occurred at a very high frequency. 1 MGY irradiation is

banded with the control at loci -1, -5, -7, -9, and -10. 4 MGY irradiation showed banding pattern with control at -3, -4 and -6 loci. But differ from 1 MGY irradiation at -1, -3, -4, -7, -8, -9 and -10. Oye Olisa accession shows a similar banding pattern with the mutant Ezi Ogidi accession. Intra class banding implies that 5 MGY irradiation shows banding with the control at locus -5 only, while 6 MGY irradiation indicated a variant mutant plant and shows no banding with the control, but differ from 5 MGY accession only at locus-5.

Table 4. Band matrix among the different accessions in relation to the associated irradiation levels.

Accessions	Band-1	Band-2	Band-3	Band-4	Band-5	Band-6	Band-7	Band-8	Band-9	Band-10
Ezi Ogidi Control	1	1	1	0	1	1	Ms	Ms	ms	Ms
Ezi Ogidi 5 MGY	0	0	0	0	0	0	Ms	Ms	ms	Ms
Ezi Ogidi 6 MGY	1	0	0	1	1	0	Ms	Ms	ms	Ms
Ogbunike Control	0	0	0	0	1	0	1	1	0	0
Ogbunike 1 MGY	0	1	1	1	0	1	0	1	0	0
Ogbunike 4 MGY	1	1	0	0	1	0	0	0	1	1
Oye Olisa Control	1	1	1	1	1	1	Ms	Ms	ms	Ms
Oye Olisa 5 MGY	0	0	0	0	1	0	Ms	Ms	ms	Ms
Oye Olisa 6 MGY	0	0	0	0	0	0	Ms	Ms	ms	Ms

Five primers were used for the preliminary study, out of which two primers (T-06 and T-20) gave the best polymorphism. The cultivar has three bands degraded with the use of 5 MGY and 6 MGY with primer T-06; the bands are 1500 bp, 1400 bp and 800 bp. This is shown on plate 1. Two primers T-06 and T-20 gave polymorphism

with Ogbunike samples. Control sample had many missing or absent bands on primer T-06 shown on plate 1. Primer T-20 had one band present on Ogbunike 1 MGY and absent on others. Ezi Ogidi samples had two polymorphic bands with primer T-06. The size of the two bands is 400 bp and 200.

8. Discussion

The exploitation of natural and induced genetic diversity inherent in crop plant species is a basic requirement for plant breeding activities. The huge pressure exerted on supporting natural resources as a result of population increase has prompted the need for proper plant genetic resource management plans to sort for relevant variations in available crop plants that can be of immense benefit to plant breeders, for crop improvement. One way of inducing variability in crop plants is by X-ray irradiation. The present research work was carried out to determine the effect of different doses of X-ray irradiation on three (3) accessions of *Amaranthus hybridus* L. using morphological and molecular (RAPD) methods.

From the morphological data, it was discovered that there was no statistical difference in three of the four parameters assessed (plant height, leaf area, and leaf number) in all accessions (Ezi-Ogidi, Ogbunike and Oye-Olisa) subjected to X-ray treatment. This finding was in line with the assertion of [21] who stated that X-ray radiation has no effect on the

seed germination or growth of *Echinacea angustifolia*. Russel [22], also recorded no difference in the plant height of *Zea mays* exposed to X-ray. Although morphological characters in *Amaranthus hybridus* are important, going by its major use as a vegetable crop, the variation induced might not be morphologically obvious but could be at the biochemical level in terms of nutrient level improvement. The wet and dry weight of the inflorescence was statistically significant. Inflorescence of *Amaranthus hybridus* is a vital part of the plant, primarily for reproduction and also for the utilization of its seeds as an important grain crop for food security. It appears to be like the different concentrations of exerted differential effects on the different accession types. Notably, Treatment 6 MGY resulting in the highest weight value of the inflorescence for Ezi-Ogidi accession, treatment 5 MGY produced the best inflorescence weight for Oye-Olisa accession. However, the treatment 1 MGY and 4 MGY did not improve the weight of Ogbunike accession. In line with this result, it is best to apply specific concentration of X-ray on the particular accession based on the requirement as regards the weight of the inflorescence. This finding is in line with the work of El-Mokadem and Mostafa [23] on

Browallia speciosa mutated with Sodium azide as well as El-Nashar [24] on *Amaranthus* seedlings and Mostafa [25] on *Heliathus annuus*.

Molecular analyses have helped resolve the distinctness in the genetic makeup of crop plants when morphological investigations have failed [26]. The present study involving the use of Random amplified polymorphic DNA has helped in identifying mutants and appropriate concentration needed for the specific accession. From the DNA result, it was noticed that Oye Olisa accession treated with 5 MGY and 6 MGY has three bands of 1500 bp, 1400 bp, and 800 bp with primer T-06 which is not noticed in the control. The Ogbunike control sample had many missing or absent bands on primer T-06, unlike the treated samples. Ogbunike accession treated with 1MGY had one band on primer T-20 which is absent on others. Ezi Ogidi accessions had two polymorphic bands of 400 bp and 200 bp with primer T-06.

The genetic variability using a distance matrix dendrogram clearly depicted in figure 2 outlines the genetic relationship among the different accessions. The dendrogram comprises 3 major groups of similar genetic make-up. The first clade is composed solely of the Ogbunike accession irradiated with 4 MGY. The second clade is composed of Ogbunike (control), Oye Olisa accession irradiated with 5 MGY and 6 MGY, and Ezi Ogidi accession irradiated with 6 MGY. The third clade comprises Ogbunike accession irradiated with 1 MGY, Ezi Ogidi accessions (control), and Oye Olisa accession (control). This genetic relationship identifies Ogbunike accession irradiated with 4 MGY as the most genetically diverse accession. And this also gives the clue on the best concentration required to induce such mutation, which in this case was 4 MGY. Various authors have suggested the use of a rapid and specific molecular marker as a workable solution to solving the problem of ambiguity resulting from the use of morphological method in assessing crop genetic variability. The advantageous use of molecular techniques in identifying variability induced by x-ray particles as compared to the morphological method has been affirmed. It offers a faster and more precise way of determining relationships among closely related species than that of the morphological investigation. These findings are in line with the report of Rahman [31] which states that DNA fingerprinting is an important tool for molecular characterization of various groups of plants. Jimoh *et al.* [27] went further to explain that morphological characteristics are subject to physiological and environmental influence. Snezana *et al.* [7] also state that the use of the RAPD assay to identify genetic variation is preferred over the morphological and biochemical markers since these are completely devoid of the effects of the environment and the stage of the experimental material, thus making them highly reliable. On the same note, Park and Nishikawa [8] states that the evaluation of morphology is very time-consuming and morphological traits often cannot serve as unambiguous markers because of environmental influence. It is worthy to also note that that

RAPD is a preferred method for identification of genotypes because it is relatively inexpensive, utilizes arbitrary primers, and randomly samples a potentially larger number of loci in a less complex pattern than other polymerase reaction (PCR) based markers [28-30].

9. Conclusion

The study has affirmed the use of x-ray particles in inducing genetic variations in *Amaranthus hybridus* accessions from Nigeria. Although most of the morphological parameters were statistically not significant except for inflorescent weight. The molecular analysis, however, showed variations, identifying polymorphism among the different accessions. The Oye Olisa accession treated with 5 MGY and 6 MGY has three bands of 1500 bp, 1400 bp, and 800 bp with primer T-06 which is not noticed in the control. The Ogbunike control sample had many missing or absent bands on primer T-06, unlike the treated samples. Ogbunike accession treated with 1MGY had one band on primer T-20 which is absent on others. This study identifies Ogbunike accession irradiated with 4 MGY as the most genetically diverse accession.

The genetic distinctness identified among accessions is largely due to chromosomal disturbances which is a consequence of the physical mutagen. This has further proven RAPD as an effective tool for the detection of genetic differences among individuals and a useful tool for breeders. The mutagenesis treatments seemed to activate the expression of some genes which resulted in the different appearances of the bands.

Future studies should involve the genetic variability assessment of the second generation mutated plants on agricultural traits such as disease resistance, pigment (leaf and grain colour), branching pattern, yield, taste, nutrition, etc.
