Abstract: Side-Chain Crystalline Block Co-Polymer (SCCBC), which is composed of a side-chain crystalline monomer unit and a functional monomer unit (which can confer solvent-compatibility, polarity, etc.), can be adsorbed to a polyethylene crystal through crystalline supramolecular interaction. By using this interaction, we can modify not only the surface but also the inner pores of a porous polyethylene membrane to give various properties. In this study, we used a monomer with ethylene oxide repeating units as a functional unit, and evaluated its potential as a solid electrolyte for use in a Li ion secondary battery. The properties of the solid electrolyte were excellent compared to those of a non-modified porous membrane at low temperature. In addition, the solid electrolyte did not show temperature-dependence, and the Li^+ ion conductivity remained nearly constant throughout the temperature range of 30°C to 60 °C. However, at high temperature (above 70 °C), the conductivity began to decrease. This characteristic may make it useful for sensing temperature and for self-controlling thermal runaway.

1. Introduction

Figure 1. Typical chemical structure of side-chain crystalline block copolymer.

It is well known that a polymer with long alkane side-chains (more than 10 carbon atoms) is a side-chain crystalline polymer [1-3]. Recently, we polymerized a block copolymer composed of a side-chain crystalline monomer unit and a solvent-compatible monomer unit (Side-Chain Crystalline Block Copolymer: SCCBC) by living radical polymerization. Figure 1 shows a typical chemical structure of SCCBC. We found that this SCCBC could be a very good dispersant of concentrated polyethylene (PE) particles dispersion systems [4-9].

This was because the side-chain crystalline unit of this block copolymer is strongly adsorbed on the PE surface, and this adsorption can be considered a form of crystalline supramolecular interaction. Figure 2 shows a schematic illustration of the mechanism of the adsorption of SCCBC on a PE surface. As a result of this adsorption, the surface of the PE particle is covered by solvent-compatible units and is easily wetted by solvent, which eliminates particle aggregation.

Figure 2. Schematic of the crystalline supramolecular interaction mechanism of the adsorption of SCCBC on a polyethylene surface. The side-chain crystalline units are adsorbed onto the PE crystalline surface and construct a pseudo crystal.

The surface of PE has generally been thought to be inert because of its high crystallinity, and no chemical group that can interact with it has been identified. For the modification of a PE surface, physical modifications (UV or plasma irradiation) have usually been carried out. However, these methods often do not result in the required properties and essentially cleave the polymer chain. Therefore, these methods decrease the mechanical properties of PE and can not be applied to a thin PE film. Furthermore, such methods can not be used to effectively modify the interior of a porous PE membrane.

Even when the solvent-compatible unit of a SCCBC is composed of polar chemical groups, the SCCBC can easily dissolve in an organic solvent because of its side-chain crystalline unit. Thus, a solution that contains the SCCBC

can penetrate into the pores of a porous PE membrane, which means that polar chemical units can be placed inside a porous PE membrane. In addition, such polar chemical units can stably remain inside the PE pores because the side-chain crystalline unit of the SCCBC is strongly adsorbed to the PE surface. In fact, since SCCBC is adsorbed so strongly, all that is necessary for SCCBC to penetrate into the pores is to place the SCCBC on a PE porous membrane and then raise the temperature to above the melting point of SCCBC.

By using this approach, we can modify a PE porous membrane to give functional membranes. In this study, we used a monomer with ethylene oxide repeating units as a functional unit, and evaluated its potential as a solid electrolyte for use in a Li ion secondary battery.

2. Experimental

2.1. Polymerization

For the side-chain crystalline monomer, we used stearyl acrylate (STA) and behenyl acrylate (BHA). For the functional monomer, we used di(ethylene glycol) ethyl ether acrylate (DEEA) and polyethylene glycol mono acrylate (PGMA). To initiate polymerization, we used 3,7-dioxa-4-aza-6-phosphonanoic acid, 4,5-bis(1,1-dimethylethyl)-6-ethoxy-2,2-dimethyl-, 6-oxide (SG-1-MA; BlocBuilder®, ARKEMA). Polymerization was performed under a nitrogen atmosphere at 105°C. The block copolymer was polymerized by sequential monomer addition. The polymerized SCCBCs and the weight average molecular weight of each unit are summarized in Table 1.

Table 1. Molecular weights of the units of SCCBCs used in this study

Sample code	Crystalline unit		Functional unit	
	Molecular specimen	Molecular weight (g/mol)	Molecular specimen	Molecular weight (g/mol)
SCCBC-1	STA	5,000	DEEA	9,500
SCCBC-2	BHA	3,000	PGMA	60,000

2.2. PE Membrane Modification

In this study, we used two PE membranes: a PE porous filter (Mykrolis®UPE, pore size 0.1μm) and a PE separator for a Li ion secondary battery (thickness 30μm, porosity 64% and

Gurle value 78sec/100cc). These membranes were modified by dipping them into dilute (0.5wt%) acetanilide SCCBC solutions. The properties of the solutions are listed in Table 2.

Table 2. Species of Porous PE Membrane, SCCBC, Solution, and Additive for Filling a Porous PE Membrane

Sample code	Species of PE porous membrane	SCCBC	Solution	Additive
mod-PE1	PE filter (Mykrolis®UPE)	SCCBC-1	acetanilide	-
mod-PE1	PE Li ion battery separator	SCCBC-2	acetanilide	lithium hexafluorophosphate (1mol/l)

In the case of the PE separator, we added lithium hexafluorophosphate to the acetanilide solution to give 1mol/l. In the case of mod-PE1, we used N,N-dimethyl acetamide as the liquid electrolyte and added lithium hexafluorophosphate to give 1mol/l. After modification, the membranes were air-dried and vacuum-dried before the conductivity measurement.

2.3. Conductivity Measurement

Li⁺ ion conductivity was measured by using an LCR-HITESTER impedance device (HIOKI 3522-50). The impedances were measured at 34 frequencies within the range of 50 to 80,000Hz. For each measurement, we made a Cole-Cole plot and determined the Li⁺ ion conductivity. The

temperature was varied from 35°C to 75°C.

3. Results and Discussion

Figure 3 shows photos of the results of dropping the modified (by dipping) and unmodified PE membranes in water. While the unmodified membrane floated on the water, the modified membrane sank. This indicates that, as a result of simple dipping in SCCBC solution, the PE membrane becomes hydrophilic not only on its surface but also in its interior.

Figure 3. Photo of unmodified (a) and modified (b) PE porous membranes in water.

Figure 4 shows a SEM image of the porous PE membrane after it was filled with the SCCBC by dipping. In the image, the pores are covered with thin films. This suggests that the SCCBC filled the pores and was stabilized due to its affinity with PE. These results show that we can easily modify the PE membrane to become hydrophilic with the use of the crystalline supramolecular interaction of SCCBC.

Figure 4. SEM image of the cross-section of a porous PE membrane modified by dipping in dilute SCCBC solution.

Figure 5 shows the temperature-dependence of the Li^+ ion conductivity of unmodified PE membrane and mod-PE1 membrane using DMAc/LiAlO₄ solution as an electrolyte. The Li^+ ion conductivity of unmodified PE membrane increased with the temperature. This is a common phenomenon, and is caused by an increase in the mobility of Li^+ ion and a decrease in the viscosity of the electrolyte. For mod-PE1, the Li^+ ion conductivity increased at lower temperature. This was because the PE membrane, which was originally hydrophobic and thus showed poor wettability with the electrolytic solution, had become hydrophilic by the

adsorption of SCCBC.

Figure 5. Temperature-dependence of Li^+ ion conductivity. Open circle shows an unmodified PE membrane used as a separator and closed circle shows a mod-PE1 membrane used as a separator.

Interestingly, for the modified PE membrane, the Li^+ ion conductivity became almost independent of temperature. Over 65°C, the conductivity began to decrease, until finally (at about 75 °C) the conductivity was almost the same as that of unmodified PE membrane. Figure 6 shows the mechanism of the change in conductivity. At low temperature, the SCCBC is adsorbed on the surface of a pore of the PE membrane, the surface becomes hydrophilic, and a Li^+ ion channel is constructed. This is why there is an increase in Li^+ ion conductivity at low temperature. At high temperature, the SCCBC is desorbed from the surface of PE, the original hydrophilic surface reappears, and the Li^+ ion channel is closed.

Figure 6. Schematic images of adsorbed and desorbed SCCBC on the pore surface of a porous PE membrane. (a) low temperature and (b) high temperature. (c) is schematic modeled SCCBC, solid line represents side chain crystalline units and dashed line represents functional units.

In a previous paper, we estimated the change in diameter by using the Hagen–Poiseuille equation (equation 1).

$$V = \frac{\pi^4 \Delta P}{8L\eta} \quad (1)$$

where ΔP : decrease in pressure, L: length of the cylindrical pore, η : dynamic viscosity, r: radius, p: mathematical constant, and V: volume of flow per unit time. V is considered to be proportional to the Li^+ ion conductivity. Therefore, the

difference in conductivity is associated with the pore diameter of the Li^+ ion channel (equation 2).

$$\frac{S_1}{S_0} = \frac{V_1}{V_0} = \left(\frac{d_1}{d_0} \right)^4 \quad (2)$$

where d_1 and d_2 are the effective pore diameters of the Li^+ ion channel.

If we apply this equation in this case, we see that, upon modification with SCCBC at low temperature, the diameter increased 1.2-fold, and the diameter decreased 0.96-fold with the desorption of SCCBC. We might be able to use this phenomenon to determine the temperature of a Li ion battery.

Figure 7. Temperature-dependence of Li^+ ion conductivity of a mod-PE2 membrane used as a solid electrolyte.

Furthermore, a battery might be able to automatically decrease its output capacity at high temperature.

Figure 8. Time- and temperature-dependence of Li^+ ion conductivity of a mod-PE2 membrane used as a solid electrolyte. The temperature was cycled between 35 °C and 39 °C. Solid lines mean heating and dashed lines mean cooling.

Figure 7 shows the solid electrolyte ability of mo-PE2 modified by SCCBC-2. The conductivity at 35 °C was $4.47 \times 10^{-4} \text{ S} \cdot \text{cm}$, which is very high. In this case, due to the side-chain crystalline unit adsorbed on the side wall of the PE pore surface, the polyoxy ethylene layer was constructed parallel to the pore side wall from the upper surface to the lower surface of the membrane.

In this case, the temperature-dependence is slightly

negative at the lower and middle temperature range and decreases rapidly at high temperature. The same mechanism that is at work in Fig. 5 may be having an effect here.

Figure 8 shows the stability of conductivity at a lower temperature range. We evaluated the conductivity under heating and cooling cycles between 35 °C to 39 °C. Within this temperature range, the conductivity is very stable. This result suggests that a PE membrane filled with SCCBC would be a very excellent solid electrolyte under normal conditions, and could decrease the conductivity at high temperature.

4. Conclusions

The SCCBC is strongly adsorbed onto PE crystal by its crystalline supramolecular interaction. It also readily dissolves in organic solvent. By using these properties, we can modify the hydrophobic property of the surface and the pores of a PE membrane simply by dipping the membrane into a SCCBC solution. The original hydrophobicity of the PE membrane can be restored at high temperature.

In this study, we modified a PE membrane so that it would exhibit Li^+ ion conductivity by using two SCCBCs with ethylene oxide structures. These modified membranes showed excellent separator and solid electrolyte properties. In addition, these membranes had specific properties which suggest that they could be used to detect a temperature change and to automatically decrease the conductivity at high temperature. These properties would be very useful for avoiding the thermal runaway of a Li ion secondary battery.

By changing the functional unit of the SCCBC and applying the associated properties, we may be able to create many other functional filters or separator membranes.
