Nadia Saleh Al-Amoudi. Effects of Dietary Protein Sources on the Progression of Renal Failure without Dialysis in Rats. *Journal of Food and Nutrition Sciences*. Vol. 1, No. 3, 2013, pp. 23-32. doi: 10.11648/j.jfns.20130103.11

Abstract: The quality and quantity of protein are essential factors that determine nutritional significance of a protein. The aim of this study was to compare the effects of several animal and plant proteins on the progression of renal failure in rats. Ninety male rats were allocated into nine groups and were fed with a basal diet containing different protein sources for 12 weeks. Two groups comprised of a negative control group and a positive control group (with induced renal failure) fed on the basal diet. Rats in the remaining seven groups were fed using different diets containing 10% protein derived from fish, meat, chicken, egg, soybean, lentil, and white bean. Biological, biochemical and histological studies were done at the end of the study. Protein content was highest for the chicken extract (87.36%), followed by meat (85.67%), egg (78.85%), and fish (78.55%). Body weight gain increased as food intake decreased in all groups other than the positive control group, and the food efficiency ratio paralleled food intake. Rats fed the fish protein diet had lower blood urea nitrogen (28.0 mg/dL), uric acid (3.5mg/dL) levels compared with the other groups. There were no significant differences in creatinine levels between rats fed the animal protein (fish and meat) or the plant protein (soy and white bean) diets. Histological studies revealed no abnormal renal features in rats fed the fish or soybean protein diets. Therefore, the results of the study suggest that a diet containing fish protein may delay the progression of chronic renal failure relative to other protein diets.

Keywords: Animal Protein, Plant Protein, Rats, Renal Failure without Dialysis, Renal Function

1. Introduction

Patients with renal failure often experience malnutrition. For instance, a study done on the impact of malnutrition on renal failure indicates that about 40% of patients with renal failure experience malnutrition [1]. Although malnutrition has a multi-factorial impact on renal failure, insufficient intake of protein significantly contributes to the occurrence of renal failure. Generally, nutritionists recommend that (CKD) should take a low-protein diet because it is beneficial; however, the source of protein is another factor that determines the progression of renal failure. While many clinicians assume that a vegan diet is better for patients with CKD, the perceived benefits of this diet may not be true because the nature of protein determines its impact on renal failure. In particular, patients consuming a vegan diet may not consume beneficial secondary nutrients that are primarily present in animal products or may consume phytates and aluminum that are present in vegetarian sources, which are harmful to patients with CKD [2]. In this view, it is advisable that patients with

CKD should consume sufficient quantities of protein that are free from harmful substances.

Patients with CKD normally undergo dialysis. Although patients may try to avoid dialysis for many years, it is important that their low-protein diet should include sufficient protein to prevent cachexia while protecting the kidneys. To manage renal failure effectively, patients with CKD should take appropriate diet has minimal nitrogenous wastes because imbalances in nitrogenous metabolites enhances morbidity and mortality of patients with CKD [3]. A prospective study of patients with non-diabetic nephropathy and moderate-to-severe renal insufficiency who consumed a vegan diet (0.7 g protein/kg/day) or an animal protein (0.6 g protein/kg/day) for a period of 3 months showed that no significant differences in creatinine clearance exist [4]. In subsequent study of 22 patients with non-diabetic nephritis, who switched from a mixed animal/vegetable diet to either a conventional low-protein diet (0.6 g protein/kg/day), or a vegan diet (0.7 g protein/kg/day); there was no marked changes in proteinuria after 4–6 months, but glomerular filtration rate

(GFR) decreased similarly in both groups [5]. A further study conducted an eight-week randomized crossover study of eight individuals with diabetes, proteinuria, and moderate renal insufficiency reported that there was a decrease in the GFR following the consumption of an animal protein diet (1 g protein/kg/day) and a soy protein diet (1 g protein/kg/day)[6]. Hence, the findings suggest that there is no advantage of a soy protein-based diet in the context of diabetic CKD.

Generally, the quality of protein can be classified into two groups; namely, low and high quality proteins. Low quality protein does not contain all essential amino acids required for use in protein synthesis whereas high quality protein contains most of the essential amino acids that is essential for the appropriate functioning of the human body system. Plant proteins are considered to be lower in quality than animal protein because they do not contain all essential amino acids. Nevertheless, protein from either source provide amino acids, which are important raw materials for the protein synthesis form component of metabolic regulators, and provide important energy [7]. Comparatively, animal proteins from food such as beef, fish, chicken, and dairy products a higher quality of protein than plant protein from food such as cereals, fruits and vegetables. Although plant and animal proteins have approximately the same types of amino acids, the proportion of the amino acids varies according to the protein sources. The nutritional quality of any protein relates to its amino acid composition, digestibility, and ability to supply the essential amino acids in the amounts required by the species consuming the protein [8]. Thus, sources of proteins determine the quality and digestibility of proteins.

Currently, some researchers recommend animal protein diets, while others advocate plant protein diets. Although several studies have been performed to compare animal protein and plant protein, very few studies have examined how proteins from different sources influence renal failure [9-13]. Therefore, it is important to compare the effects of different protein sources on renal function to determine their suitability to patients with renal failure. Consequently, the objective of the study was to compare the effects of several animal and plant protein diets on the biochemical and histopathological characteristics of rats with chemically induced chronic renal failure.

2. Materials and Methods

2.1. Materials

2.1.1. Food Items

Fish fillet, ground beef meat, chicken breast, lentil, and

white bean were obtained from a local market (Jeddah, Saudi Arabia). Soybean and egg protein (pure albumin) were purchased from a local market in Cairo (Egypt). The researcher cleaned and milled all food items into a fine powder before using them at 10% in the diet, instead of the main source of protein in the basal diet (casein), according to the percent of protein of each food item.

2.1.2. Gentamicin

Obtained from Al-Nahdy pharmacy.

2.1.3. Rats

Purchased them from the Pharmacy College at King Saud University.

2.2. Methods

2.2.1. Chemical Composition

Crude protein, moisture, fat, fiber, and ash contents of each protein source were determined according to methods outlined by the Association of Official Analytical Chemists AOAC [14]. Carbohydrate content was determined using standard analytical procedures for the sake of accuracy.

2.2.2. Biological Investigation

Male albino rats Sprague Dawley strain (90 rats) weighing 130–150g were obtained from the Pharmacy College at King Saud University and were delivered to the King Fahd Medical Research Center in Jeddah. To enable rats acclimatize the new experimental environment, they were kept in well-aerated cages for a period of one week and fed on basal diet. The composition of the basal diet was 1% vitamin, 4% salt, 5% cellulose, 10% corn oil, 10% casein, and 70% cornstarch, as recommended in the protocol [15].

2.2.3. Preparation of Renal Failure without Dialysis Rats

Renal failure without dialysis was induced in normal healthy male albino rats via intra-peritoneal injection of gentamicin at a dose of 100 mg /kg b. wt. for 7 days according to the evidence-based method [16].

2.2.4. Experimental Design

The study assigned 90 rats nine groups. The first group of rats was fed on basal diet and they acted as a negative control, while the rest 80 rats assigned to 8 groups acted as a positive control because they have renal failure without dialysis. The 90 rats were divided into nine groups (n=10) according to the following scheme:

Group (A): non-renal failure control (negative control): one group

Group (B): Renal failure without dialysis main groups: 8 groups

Groups	Treatment	Diet	Period
1	Non renal failure control	Basal diet	12 weeks
2	Renal failure without dialysis main groups	Basal diet	12 weeks
3	Renal failure without dialysis main groups	Basal diet + 10% fish	12 weeks
4	Renal failure without dialysis main groups	Basal diet + 10% meat	12 weeks
5	Renal failure without dialysis main groups	Basal diet + 10% chicken	12 weeks
6	Renal failure without dialysis main groups	Basal diet + 10% egg	12 weeks
7	Renal failure without dialysis main groups	Basal diet + 10% soya bean	12 weeks
8	Renal failure without dialysis main groups	Basal diet + 10% lentil	12 weeks
9	Renal failure without dialysis main groups	Basal diet + 10% white bean	12 weeks

The following table shows the composition of the experimental diets according to the percentage content of proteins in different food sources relative to casein.

Table (1): Composition of the experimental diets

Composition	Casein	Fish	Meat	Chicken	Egg	Soy	Lentil	White bean
Protein	100	127	117	114	127	195	397	422
Corn oil	100	87	95	96	99	90	95	96
Corn starch	353	339	341	343	327	268	61	35
Sucrose	350	350	350	350	350	350	350	350
Cellulose	50	50	50	50	50	50	50	50
Salt mix	35	35	35	35	35	35	35	35
Vitamin	10	10	10	10	10	10	10	10
Choline bitartrate	2	2	2	2	2	2	2	2

During the experimental period of 12 weeks, the diet consumed was recorded every day, while body weight was recorded every week. Since different protein sources have different impacts on renal failure, rats were fasted overnight before they were slaughtered. During slaughter, blood samples were collected and stored in clean centrifuge tube where they were left for 15 minutes to clot. Thereafter, the clotted blood samples were centrifuged to obtain serum at 3000 rpm for 15 minutes. Additionally, to examine the levels of various metabolites in the body, vital organs such as liver, spleen, lung, heart, and kidney were excised, weighed individually, and preserved in the fridge for pathological analysis.

2.3. Biological Evaluation

During the experimental period, the weights of all rats were determined weekly and recorded. At the end of the experimental period, body weight gained in percentage (BWG %) and Food Efficiency Ratio (FER) was determined as a biological evaluation according to the following formulas [17].

$$\text{BWG \%} = \frac{\text{Final weight} - \text{Initial weight}}{\text{Initial weight}} \times 100\%$$

$$\text{FER} = \frac{\text{Gain in body weight (g)}}{\text{Food intake (g)}}$$

2.3.1. Analytical Methods

Serum creatinine, serum uric acid, and blood urea nitrogen (BUN) levels, as markers of renal function, were determined using the biochemical methods described by three scientists respectively [18, 19, 20].

Additionally, serum total protein and serum albumin levels were determined using the methods described by two scientists respectively [21, 22].

The level of serum globulin was determined using total protein and albumin, as the difference of the two metabolites. The levels of potassium (K) and sodium (Na) were calculated basing on the standard formula that is recommended [14].

2.4. Histopathological Study

To examine the impacts of protein diets on vital organs such as kidneys, lungs, liver, spleen, and heart, the organs were fixed using 10% formalin, which is buffered at neutral PH, dehydrated in ethyl alcohol, then cleared in xylol and embedded in paraffin. Subsequently, 4-6 microns thickness sections prepared and stained with hematoxylin and eosin for examining the liver using a light microscope at various magnifications [23].

2.5. Statistical Analysis

Data were compared between the 10 groups using analysis of variance (ANOVA) by following statistical

analysis procedure in the book. In the comparative analysis, the means were compared at least significant difference level of 0.05 as described in statistical analysis [25].

3. Results and Discussion

Since proteins affect renal function, regulation of dietary proteins has proved to be essential in preservation of renal function. In addition to quantity, the quality of dietary protein is thought to affect renal function; however, the effects of protein on the renal function are still poorly understood. Thus, the study sought to establish the effect of protein quality on renal function by ascertaining differential impacts of plant and animal proteins on the progression of renal failure. In this view, the results of the present study revealed that out of all the animal and plant proteins tested, fish protein had the best effects of preventing the progression of renal failure among rats without dialysis.

3.1. Chemical Composition of Protein Sources

In the present study, dried fish, meat, chicken, egg,

soybean, lentil and white bean were analyzed for their contents of moisture, fat, protein, fiber, ash and total carbohydrate, the results are given in table (2). The data show that moisture, fat, protein, fiber, ash and total carbohydrate content of fish is 4.36%, 10.27%, 78.55%, 0.11%, 6.04%, and 0.67% respectively, while that of meat is 1.75%, 4.48%, 85.67%, 0.09%, 2.79%, and 5.22% respectively. Moreover, the moisture, fat, protein, fiber, ash and total carbohydrate content of chicken is 5.29%, 3.53%, 87.36%, 0.19%, 3.11%, and 0.52%, while that of an egg is 7.88%, 0.25%, 78.85%, 0.26%, 5.23%, and 7.53%. For soya bean, it is 3.40%, 5.19%, 51.24%, 3.09%, 6.50%, and 30.58%, for lentil it is 8.09%, 1.32%, 25.18%, 1.48%, 1.41%, and 60.52%, and ultimately for white bean is 5.49%, 1.02%, 23.71%, 5.22%, 3.16% and 61.40% respectively. The data reveal that the protein content of animal sources is higher than plant sources. The highest content is present in chicken while the lowest content is present in white bean. These results are in agreement with the finding that recommends a target dietary protein content of 0.6–0.75 g/kg/day for patients with CKD [26].

Table (2): Chemical composition of fish, meat, chicken, egg, soybean, lentil, and white bean

Foods Components	Fish %	Meat %	Chicken %	Egg %	Soybean %	Lentil %	White bean %
Moisture	4.36	1.75	5.29	7.88	3.40	8.09	5.49
Fat	10.27	4.48	3.53	0.25	5.19	1.32	1.02
Protein	78.55	85.67	87.36	78.85	51.24	25.18	23.71
Fiber	0.11	0.09	0.19	0.26	3.09	1.48	5.22
Ash	6.04	2.79	3.11	5.23	6.50	1.41	3.16
T. carb.	0.67	5.22	0.52	7.53	30.58	62.52	61.40

3.2. Biological Evaluation

3.2.1. Effect of Protein Sources on BWG, FI, and FER for Renal Failure without Dialysis Rats

Data presented in table (3) show the effect of fish, meat, chicken, egg, soybean, lentil and white bean on body weight gain (BWG), food intake (FI), and feed efficiency ratio (FER) in rats with renal failure without dialysis.

Table (3): Effect of fish, meat, chicken, egg, soybean, lentil and white bean on body weight gain (BWG) food intake (FI), and feed efficiency ratio (FER) of renal failure without dialysis rats.

Parameters Animal group	BWG (g)	FI (g)	FER
Control (-)	0.71 ± 0.05 a	10.08 ± 0.23 d	0.070 ± 0.011 a
Control (+)	0.33 ± 0.03 g	18.58 ± 0.18 a	0.018 ± 0.014 f
Fish	0.63 ± 0.01 b	10.98 ± 0.24 d	0.057 ± 0.013 b
Meat	0.62 ± 0.01 d	12.83 ± 0.29 b	0.036 ± 0.017 d
Chicken	0.48 ± 0.02 d	10.46 ± 0.09 d	0.046 ± 0.010 c
Egg	0.44 ± 0.01 d	12.07 ± 0.09 b	0.036 ± 0.012 d
Soybean	0.54 ± 0.62 c	12.41 ± 0.23 b	0.044 ± 0.016 c
Lentil	0.36 ± 0.02 e	12.48 ± 1.18 b	0.029 ± 0.015 e
White bean	0.63 ± 0.03 b	11.61 ± 0.18 c	0.054 ± 0.011 b

Values denote arithmetic means ± standard deviation of the means at $p \leq 0.05$.

It could be observed from Table (3) that body weight gain for renal failure without dialysis rats (C +ve group) was 0.33 ± 0.03 compared to 0.71 ± 0.05 g/day in (C -ve) normal rats. These results denote that there was significant decrease in BWG of renal failure without dialysis rats as compared to the normal rats. Rats with renal failure without dialysis and fed on all tested protein sources showed significant increase in weight when compared to control positive group. Rats of renal failure without dialysis and fed on fish and white bean showed the highest significant increase in BWG when compared to control positive group, while groups fed on meat, chicken and egg showed the lowest significant decrease in BWG when compared to control positive group.

Concerning food intake (FI), there was a significant increase in control positive group compared to normal rats ($P < 0.05$), which were 18.58 ± 0.18 and 10.0 ± 0.23 respectively. All experimental groups showed a significant decrease when compared to positive group. Rats with renal failure without dialysis and fed on fish and chicken showed the highest significant decrease in FI when compared to the positive control group, and at the same time, these groups revealed no significant changes when compared to normal rats.

Regarding the feed efficiency ratio (FER), the positive control group had 0.018 ± 0.014 , while the negative control

group had 0.070 ± 0.011 . The obtained results showed that there was significant decrease in the feed efficiency ratio in the positive control group as compared to the negative control group. In rats with renal failure without dialysis, which was fed on fish and white bean showed the highest significant increase in FER when compared to the positive control group. These results confirm by the findings, which demonstrate that even patients with a mild decline in GFR (i.e., <50 mL/min) show decreases in their calorie and protein intake as dietary protein intake progressively declines with decreasing GFR [1]. Similarly, a study reported that there is a limited decrease in food intake from 7.26 to 7.15 g/day (not significant) in normal rats and from 18.61 to 14.72 g/day (significant) in rats with renal impairment [27].

3.2.2. Effect of Protein Sources on Kidney Functions (Creatinine, Blood Urea Nitrogen BUN, and Uric Acid) in Renal Failure without Dialysis Rats

Data presented in table (4) show the effect of fish, meat, chicken, egg, soybean, lentil, and white bean on creatinine, blood urea nitrogen BUN, and uric acid on rats with renal failure without dialysis.

Table (4): Effect of fish, meat, chicken, egg, soybean, lentil, and white bean on creatinine, blood urea nitrogen BUN, and uric acid of renal failure without dialysis rats

Parameters Animal group	Creatinine (mg/dL)	BUN (mg/dL)	Uric acid (mg/dL)
Control (-)	0.60 ± 0.05 d	33.00 ± 2.00 f	3.50 ± 0.10 g
Control (+)	1.30 ± 0.11 a	85.80 ± 2.55 a	5.20 ± 0.21 a
Fish	0.83 ± 0.06 c	28.00 ± 0.19 g	3.50 ± 0.13 g
Meat	0.87 ± 0.02 c	39.00 ± 0.13 e	4.10 ± 0.11 f
Chicken	1.00 ± 0.15 b	32.00 ± 0.25 f	4.40 ± 0.23 c
Egg	0.64 ± 0.04 d	38.00 ± 0.27 e	4.20 ± 0.16 e
Soybean	0.80 ± 0.12 c	55.00 ± 1.55 d	4.30 ± 0.20 d
Lentil	1.00 ± 0.13 b	58.00 ± 2.11 c	4.50 ± 0.25 b
White bean	0.90 ± 0.10 c	66.00 ± 2.17 b	4.40 ± 0.17 c

Among rats with renal failure without dialysis rats, it is apparent that the positive control group had creatinine, urea level and uric acid levels of 1.30 ± 0.11 , 85.80 ± 2.55 and 5.20 ± 0.21 mg/dL, while in normal rats had 0.60 ± 0.05 , 33.00 ± 2.00 and 3.50 ± 0.10 mg/dL respectively. These findings show that there is a significant increase ($P < 0.05$) for all of previous mentioned parameters in the positive control group as compared to the negative control group. All rats with renal failure without dialysis and fed on all sources of proteins show significant decrease in creatinine, urea and uric acid. In egg, chicken and fish groups, they exhibit the highest significant decrease ($P < 0.05$) in creatinine, urea and uric acid respectively, and at the same time these groups reveal non-significant when compared to negative control groups (normal rats).

Another study, which examined the toxicity of urea among dialyzed patients, found out that if BUN levels approach 140 mg/dL and remain constant for about one week, they cause uremic symptoms [28]. However, moderately high BUN is associated with a few symptoms in individuals with otherwise normal renal function. Therefore, the levels of BUN in the body determine protein intake and reflect the clearance of urea. The relationships between BUN levels and protein intake exist because urea is a product of amino acid catabolism. The major parameter that indicates abnormality in urea metabolism is an increased level of ammonia in arterial blood [29]. Normally, the body can excrete urea via the kidneys, dissolve in the body water, or undergo metabolism into ammonia by gut bacteria. In the body, loss and intake of nitrogen are almost constant; hence, there is not a net loss [30]. A study of individuals with diabetic nephropathy revealed that a soy protein diet has no beneficial impact on proteinuria or renal failure without dialysis [6].

3.2.3. Effect of Protein Sources on Serum Protein Fractions (Total Protein, Albumin, Globulin, and Albumin/Globulin Ratio) for Renal Failure without Dialysis Rats

Table (5) shows the effect of fish, meat, chicken, egg, soybean, lentil, and white bean on total protein (T.protein), albumin, globulin, and (albumin globulin (A /G) ratio) of rats with renal failure without dialysis.

Table (5): Effect of protein sources on serum protein fractions (Total protein, albumin, globulin, and albumin/globulin ratio) for renal failure without dialysis rats

Parameters Animal group	T. protein (g/dL)	Albumin (g/dL)	Globulin (g/dL)	A/G Ratio
Control (-)	9.30 ± 0.21 a	5.60 ± 0.11 a	3.70 ± 0.12 b	1.52 ± 0.52 a
Control (+)	7.80 ± 0.24 d	4.00 ± 0.22 g	3.80 ± 0.20 a	1.05 ± 0.66 d
Fish	7.90 ± 0.11 cd	4.50 ± 0.23 e	3.40 ± 0.23 e	1.32 ± 0.71 c
Meat	7.90 ± 0.12 cd	4.20 ± 0.21 f	3.70 ± 0.14 b	1.13 ± 0.63 d
Chicken	8.40 ± 0.21 b	4.80 ± 0.13 b	3.60 ± 0.10 c	1.33 ± 0.55 c
Egg	7.90 ± 0.23 cd	4.70 ± 0.24 c	3.20 ± 0.24 g	1.47 ± 0.88 a
Soybean	7.90 ± 0.20 cd	4.60 ± 0.14 d	3.30 ± 0.21 f	1.39 ± 0.95 b
Lentil	8.00 ± 0.13 c	4.50 ± 0.11 e	3.50 ± 0.13 d	1.28 ± 0.10 c
White bean	7.90 ± 0.14 cd	4.20 ± 0.20 f	3.70 ± 0.10 b	1.14 ± 0.99 d

It is clear from the table that total protein for renal failure without dialysis rats (C +ve group) was 7.80 ± 0.24 compared to 9.30 ± 0.21 g/dL in (C -ve) normal rats. These findings indicate that there is a significant decrease in total protein of rats with renal failure without dialysis as compared to normal rats. All rats of renal failure without dialysis and fed on all tested protein sources reveal a significant increase in total protein when compared to control positive group. Chicken group shows the highest significant increase in total protein as compared to the negative control group. Albumin for control positive group is 4.00 ± 0.22 g/dL, showing significant decrease when compared to the negative control group, which is 5.60 ± 0.11 g/dL. All groups show significant increase in serum albumin when compared to control positive group. Additionally, the chicken group shows that it has the highest significant increase in the albumin levels than in all cases of the negative control group.

Globulin for control positive group was 3.80 ± 0.20 g/dL, showing a significant increase when compared to C -ve the normal rats which was 3.70 ± 0.12 g/dL. Among all groups, positive control group shows the highest significant decrease in serum albumin. It is apparent from the table that groups of fish, chicken, egg, soybean and lentil show a significant decrease in globulin not only when compared to the positive control group, but also when compared to the negative control group, thus revealing their role in decreasing globulin in serum as an enhancement for kidney status.

Concerning (albumin globulin A/G) ratio there is a significant decrease in the positive control group when compared to normal rats ($P < 0.05$), which are 1.05 ± 0.66 and 1.52 ± 0.52 respectively. Groups of fish, chicken, egg, soybean, and lentil show a significant increase when compared to the positive control group. Unfortunately, rats with renal failure without dialysis and fed on meat and white bean show no significant changes in A/G ratio when compared to the positive control group.

Serum albumin and transferrin levels are widely used to assess nutritional status of an individual [31]. When assessing serum albumin, clinicians should consider that its concentration is determined by many factors, including the synthesis, catabolism, excretion of albumin, changes in plasma volume, and distribution between extracellular and intravascular spaces. In addition, it was reported that albumin could shift into the intravascular compartment. Albumin synthesis and catabolism may also be decreased in malnourished non-uremic subjects, as well as in chronically uremic and nephrotic patients [32]. Consequently, among non-uremic subjects, it is difficult to ascertain total albumin level. Providentially, difference in half-life between transferrin and albumin is a critical indicator of malnutrition because transferrin has a shorter half-life than albumin [33]. However, the transferrin levels vary with hydration and protein turnover; hence, may be affected by inflammation and/or changes in iron stores.

3.2.4. Effect of Protein Sources on Serum Na and K Levels for Renal Failure without Dialysis Rats

Data illustrated in table (6) show the effect of fish, meat, chicken, egg, soybean, lentil, and white bean on Na and K in renal failure without dialysis rats.

Table (6): Effect of protein sources on serum Na and K levels for renal failure without dialysis rats

Parameters Animal group	Na (Mmol/L)	K (Mmol/L)
Control (-)	74.00 ± 1.00 e f	10.00 ± 1.00 a
Control (+)	165.00 ± 5.00 a	4.00 ± 0.50 e
Fish	85.00 ± 2.00 d	8.20 ± 0.72 b
Meat	91.30 ± 3.25 c	6.08 ± 1.88 cd
Chicken	84.80 ± 1.59 d	5.00 ± 0.55 de
Egg	76.80 ± 1.58 e	4.72 ± 0.63 de
Soybean	72.50 ± 2.55 f	4.70 ± 0.11 d e
Lentil	90.00 ± 5.11 c	6.50 ± 0.25 c
White bean	96.00 ± 2.13 b	8.80 ± 0.19 ab

From the data in the table, renal failure without dialysis rats (control positive groups) showed a significant increase ($P < 0.05$) in Na while showed a significant decrease ($P < 0.05$) in K when compared to control -ve normal rats which were 165.00 ± 5.00 and 74.00 ± 1.00 Mmol/L for Na and were 4.00 ± 0.50 and 10.00 ± 1.00 Mmol/L for K respectively. All rats of renal failure without dialysis and fed on all tested protein sources revealed significant decrease in serum Na while showed significant increase when compared to control positive group. Soybean group showed the highest significant decrease in serum Na as compared to control positive group and showed no significant changes as compared to normal rats. Chicken group showed the highest significant increase in total protein as compared to control -ve group. Early studies revealed that patients with chronic renal failure without dialysis and severe uremia experienced marked symptomatic improvements following dietary protein restricted, prompting its recommendations for dietary therapy [34].

Biochemists have elucidated mechanisms of amino acid metabolism and have found out that the accumulation of inorganic ions and nitrogenous waste products predisposes people to uremia due to clinical and metabolic disturbances. Dietary protein restriction has been used to treat this disorder because excess dietary protein, unlike carbohydrate and fat, is not stored, but is instead degraded to urea and other waste products, which accumulate in patients with impaired renal function. Dietary restriction of protein aids in regulation of potassium, sodium, phosphates, and other ions in the body because proteins contain many ions. Although protein restriction therapy is effective in improving renal failure, insufficient protein intake causes degradation of endogenous protein stores, which help in the

loss of lean body mass among patients with uremia who are under excessive protein-restricted diets [35]. Differences in amino acid composition explain differential of various proteins on renal function. For instance, the difference between the fish and casein protein is the composition of arginine as fish protein has double proportion of arginine relative to the casein. The mechanism of fish protein is that it inhibits HMG-GA reductase by raising plasma arginine levels and consequently the glucagon level [36]. Moreover, fish protein has more sulfur because cysteine and methionine are sulfur-containing amino acids. Diets rich in cysteine and methionine amino acids are beneficial because they reduce cholesterol levels in rats [36, 37].

The other part could be accompanying of complete protein and fish oil. Fish oil is rich in omega 3 fatty acids, several studies indicate that supplementation with fish oil rich in (n-3 PUFA) has beneficial effects on the renal insufficiency. A study demonstrated that the fully defatted fish protein diet does not improve the renal failure compared with the control casein diet in spontaneously hypercholesterolemic rats, whereas a semi-defatted fish protein diet can improve renal function [12]. This suggests that the beneficial effect of the fish protein diet depends on the accompanying fish oil since the fish protein source includes 10% fat as shown in table 1. Clinical and epidemiological studies have shown that fish oil has beneficial effects on the cardiovascular system. Researchers have reported that fish oil prevents hypertension because it lowers blood pressure [38, 39, and 40]. Other researchers have also found similar findings and reported that fish oil is important in the management of cardiovascular disorders [41, 42]. Therefore, since the findings are relevant to humans, their extrapolation means that consumption fish diet or oil is necessary for patients with chronic renal diseases to manage their conditions. Moreover, since fish diet or oil improves prognosis cardiovascular disorders, it is

recommendable that people should use of fish diet in prevention and management of cardiovascular diseases. Thus, further research should continue to study how different protein sources affect renal failure in humans.

3.3. Histological Results

As expected, the kidneys from rats in the negative control group had normal histological features of the renal parenchyma (Fig. 1). By contrast, the kidneys from the positive control group showed congestion of the renal blood vessels (Fig. 2). No histopathological changes were observed in the kidneys of rats fed the fish protein diet (Fig. 3). Kidneys from rats fed the meat protein diet exhibited hypertrophic glomerular tufts (Fig.4). Vacuolar degeneration of the endothelial cells in the glomerular tufts was observed in the kidneys from rats fed the chicken protein diet (Fig.5). The kidneys from rats fed the egg protein diet also exhibited vacuolar degeneration of epithelial cells in the renal tubules and the glomerular tufts (Fig. 6). No histopathological changes were observed in the kidneys from rats fed the soybean diet (Fig.7). Finally, the kidneys from rats fed the lentil or white bean protein diets exhibited congestion of the tubular capillaries (Fig.8) and of the renal blood vessels (Fig.9).The present study revealed that no histopathological changes in the kidneys of rats fed the fish or soy protein diets existed; hence, suggesting that these diets did not affect kidney tissues. These results also suggest that the fish protein and soy protein diets may improve the pathological changes in the renal parenchyma of rats with renal failure. These are consistent with the findings, which reported that low-protein diets protected against histological damage and exhibited improved mortality compared with other diets in rats with experimental chronic renal failure [43].

Fig (2): Kidney of rat from group 2 showing vacuolar degeneration of epithelial lining renal tubules and endothelial lining glomerular tufts (H and E x 200).

Fig (3): Kidney of rat from group 3 showing no histopathological changes (H and E x 200).

Fig (4): Kidney of rat from group 4 showing hypertrophy of glomerular tufts (H and E x 200).

Fig (5): Kidney of rat from group 5 showing vacuolations of endothelia lining glomerular tufts (H and E x 200).

Fig (6): Kidney of rat from group 6 showing vacuolations of epithelial lining renal tubules and endothelial lining glomerular tufts (H and E x 200).

Fig (7): Kidney of rat from group 7 showing no histopathological changes (H and E x 200).

Fig (8): Kidney of rat from group 8 showing congestion of intertubular blood capillaries (H and E x 200).

Fig (9): Kidney of rat from group 9 showing congestion of renal blood vessels (H and E x 200).

4. Limitation

In this research I did not find a mechanism explains the role of fish protein in improving renal failure without dialysis, therefore, the study suggested that the effective impact is due to the quality, percentage, and metabolism of amino acids in fish according to the results.

5. Conclusion

This study revealed that a low protein diet containing fish protein slowed the progression of chronic failure in rats to a greater degree than the diets containing other protein sources.

Acknowledgments

The author thanks Prof. Mansour Suliman, the manager of King Fahad Medical Research Center and Dr. Taha Qumusani, Vice Manager of King Fahad Medical Research Center for their support and Dr. Huda Abu-Araki,

Prof.Dr.Fatmaa-AlZhraa Elsharief, Dr. El-Sayed Hamed Assistant Prof. Clinical Nutrition Dept., Faculty of Applied Medical Sciences., Umm Al-Qura University for their help and support during the experimental period.
