Abstract: Pure Poly (methylmethacrylate) (PMMA) polymer film and Celestin Blue B dye doped polymer films at different concentrations were prepared using casting technique. UV - Vis spectra were recorded to characterize the optical properties of the Celestin Blue B dye doped PMMA polymer films. The magnitudes of both real and imaginary parts of third - order nonlinear susceptibility ($\chi^{(3)}$) of Celestin Blue B dye doped polymer films were determined using the z - scan technique with a continuous wave laser beam at wavelength 532 nm. The nonlinear refractive index (n_2) and the nonlinear absorption coefficient (β) of the Celestin Blue B dye doped polymer films were calculated. It was found that the prepared films exhibited saturable absorption (SA) and self - defocusing effect. The optical power limiting behavior also investigated for Celestin Blue B dye doped PMMA polymer films at different concentrations and the optical power limiting threshold values were determined. Results indicate that the Celestin Blue B dye doped PMMA polymer film is a promising material for future photonic device applications.

1. Introduction

Materials with high nonlinear optical (NLO) properties have received much attention recently due to their great potential in many important applications such as, optoelectronic and photonic devices, optical communications, optical signal processing, optical solar cells, optical sensors, light-emitting diodes (LED's), optical switching, and optical power limiting [1-15]. The protection of the human eyes and sensitive optical equipment from potentially intense laser beams are particularly important and required efficient control of the intensity of the incident laser beam. It has been found that the intensity of the laser beam can be controlled by using the optical power limiting properties of some nonlinear materials. Several materials have been investigated for their nonlinear optical (NLO) properties, and organic materials such as dyes and polymers

have emerged as promising NLO materials [16 - 24]. These kinds of materials are found to exhibit good nonlinear optical properties and fast responses in the ultraviolet and visible (UV-Vis.) spectral domain. The wide range of polymer applications can be even more extended by the modification of their physical properties by the addition of organic dye to the polymer (as doping agent). Poly (methylmethacrylate) (PMMA) polymer, which we have chosen for the present work, is one of the important polymeric materials and it is widely used in various applications for its many advantageous properties such as: Highly light transmission (transparent material), flexible structure, ease of fabrication, good photo-thermal stability, and high damage threshold for the intense laser beams [10, 25, 26], as well as it has a relatively low cost. PMMA polymer can be modified by incorporating different additives. These polymer modifications are typically

performed to improve the optical and electrical properties of the polymer, targeted toward the photonic device applications. In the present work, Celestin Blue B dye has been used as an additive (or a dopant) material to PMMA polymer to obtain a structure in the form of dye doped polymer film. The results showed that the optical and electrical properties of the pure PMMA polymer are significantly affected by introducing the Celestin Blue B organic dye into PMMA polymer. Among the various techniques used to measure the optical parameters of nonlinear materials [27-32], the z-scan technique [33, 34] proved to be an effective tool. This technique can be used to measure both nonlinear refractive index (n_2) and nonlinear absorption coefficient (β) in materials. The obtained values of these parameters can be used to determine the magnitudes of both real and imaginary parts of third-order nonlinear susceptibility ($\chi^{(3)}$) of Celestin Blue B dye doped PMMA polymer films. The z-scan technique can also be used to measure the optical power limiting behavior of Celestin Blue B dye doped PMMA polymer films.

In the current work, the nonlinear optical properties of Celestin Blue B dye doped PMMA polymer films at different concentrations were investigated using the z - scan technique with CW laser beam. The nonlinear optical parameters such as, the nonlinear refractive index (n_2), the nonlinear absorption coefficient (β), and the real and imaginary parts of third-order nonlinear susceptibility ($\chi^{(3)}$) of Celestin Blue B dye doped PMMA polymer films were determined. Effect of variation the dye concentration on the values of these parameters was studied. The optical power limiting behavior of Celestin Blue B dye doped PMMA polymer films was also studied.

2. Materials and Experimental Procedures

2.1. Preparation of the Samples

The chemical structure of Celestin Blue B dye is shown in Figure 1 and its molecular formula is $C_{17}H_{18}ClN_3O_4$ with a molecular weight $M_w = 363.80$ g / mole. Poly (methylmethacrylate) (PMMA) polymer in the form of small grains (crystalline polymer) was used in this study. It has high purity and good optical transparency, with a molecular weight $M_w = 84000$ g / mole. Samples of dye - doped polymer films were prepared using the casting technique. Certain weight of Celestin Blue B dye powder was dissolved in a mixed solution of Tetrahydrofuran (THF) with a small quantity of methanol; this is suitable solvent for both dye and PMMA polymer. Then required weight of pure PMMA polymer was added. The mixture was stirred using a magnetic stirrer till a clear solution was formed. This solution was diluted by the solvent and samples of solutions with

different dye concentrations were obtained. Proper quantities of the prepared solutions were poured on thin glass slides and kept for drying for 48 hours at room temperature. Dye - doped polymer film samples of different concentrations (0.05, 0.06, 0.07, 0.08, and 0.09 mM) and an average thickness of 0.9 mm; were obtained. The prepared polymer films were examined carefully and found that are uniform with good optical quality.

Figure 1. Chemical structure of Celestin Blue B dye.

2.2. Experiments

The z - scan experiments setup is shown in Figure 2. A linearly polarized Gaussian TEM₀₀ beam of a continuous wave (CW) solid - state laser (SSL) operating at wavelength $\lambda = 532$ nm was used. The power of the laser can be varied over the range 0 - 100 mW. To perform the z - scan measurements, the laser Gaussian beam was focused into the sample to a beam waist $\omega_0 = 18$ μ m using convex lens of focal length 5 cm, producing a peak value of the on z - axis intensity at focus $I_0 = 4.32$ kW / cm². The Rayleigh range (Z_R) (or the diffraction length) was calculated to be 1.91 mm, and hence the sample of path 0.9 mm satisfies the thin medium condition in the z - scan technique, that is the sample thickness (L) less than the Rayleigh range (i.e., $n_0 L < Z_R$, where n_0 is the linear refractive index of the sample) [35]. An aperture of variable diameter placed in the far field is used to control the cross-section of the laser beam coming out of the sample. In our present work, we adjusted the diameter of the aperture as to get the optimum value of the linear transmittance, $S = 0.32$ (i.e., 32% of the laser beam transmission allowed to pass through the aperture). The sample was scanned across the focal plane of the lens along the propagation of the laser beam (the z - axis direction) using translation stage. The power of the transmitted laser beam through the aperture was measured by the photo - detector PD₂, coupled with digital power meter. The input power of the laser beam was measured by the photo-detector PD₁, coupled with another digital power meter. The beam splitter (BS) was used to reflect part of the incident laser beam on the photo - detector PD₁.

Figure 2. Experimental set-up for the z - scan technique. BS, is a beam splitter; PD_1 and PD_2 are Photo - detectors.

3. Results and Discussion

3.1. UV - Vis Spectroscopic Characterization

The Ultraviolet - Visible (UV - Vis) absorbance spectra of the Celestin Blue B dye - doped polymer film samples at five different concentrations (0.05, 0.06, 0.07, 0.08, and 0.09 mM) were recorded over the wavelength range 300 - 900 nm using double - beam spectrophotometer (Cecil Model CE - 7500) of the wavelength range 190 - 1100 nm.

These spectra are shown in Figure 3. It is noticed that all the peaks of the absorbance curves are located at the wavelength 605 nm and the highest value of the measured optical absorbance is 16.8% for the dye - doped polymer sample with the dye concentration 0.09 mM. It is also noticed that the film samples exhibit high transmittance at low dye concentrations, and it is decreased as the dye concentration increases.

Figure 3. UV - Vis absorbance spectra of the Celestin Blue B dye - doped polymer films at different dye concentrations.

3.2. Nonlinear Measurements

The z - scan measurements for the Celestin Blue B dye - doped polymer film at different dye concentrations are shown in Figure 4 (a - c). Plot (a) is the closed - aperture z - scan and plot (b) is the open - aperture z - scan, where the normalized transmittance is plotted as a function of the sample position along the z - axis. It is clearly seen that the transmittance curves obtained are symmetric about focus for all sample concentrations, and this indicates that the studied sample follows the thermal nonlinear process. Since the closed-

aperture transmittance is affected by both the nonlinear refraction and absorption, therefore it is necessary to separate the effect of the nonlinear refraction from the nonlinear absorption in order to determine the nonlinear refractive index (n_2). To obtain purely nonlinear refraction, the closed-aperture transmittance data are divided by the corresponding open-aperture transmittance data [34]. The obtained pure nonlinear refraction curves for different dye concentrations are shown in Figure 4 (c). It is obvious from the closed-aperture, the film samples exhibited a transmission peak to valley is indicative of a negative nonlinear refractive index ($n_2 < 0$) due to self-defocusing effect. This behavior is attributed to a thermal nonlinearity resulting from the local variation of refractive index (n) of the medium with temperature (T) (i. e., dn/dT). As a result, the medium acts as a thermal lens.

Figure 4. Normalized transmittance curves for the Celestin Blue B dye - doped polymer film at different dye concentrations. (a) Closed - aperture z - scan. (b) Open - aperture z - scan. (c) Pure nonlinear refraction.

Also, it is seen in the Figure 4 (a) that as the film sample is moved towards the focus (from $-z$ to $+z$), the intensity (transmittance) increases until reaches its maximum value at the focus ($z = 0$), (valley position) indicating saturable absorption (SA) [36]. This suggests that the value of the nonlinear absorption coefficient (β) is negative ($\beta < 0$).

The real part ($\text{Re}(\chi^{(3)})$) and the imaginary part ($\text{Im}(\chi^{(3)})$) of the third - order nonlinear optical susceptibility ($\chi^{(3)}$) for the Celestin Blue B dye - doped polymer film were calculated from the estimated values of the nonlinear refractive index n_2 (obtained from the closed - aperture z - scan data) and the nonlinear absorption coefficient β (obtained from the open - aperture z - scan data), using the following relations, respectively [37]:

$$\text{Re}[\chi^{(3)}](\text{esu}) = 10^{-4} \frac{\epsilon_0 c^2 n_0^2}{\pi} n_2 (\text{cm}^2 / \text{W}) \quad (1)$$

$$\text{Im}[\chi^{(3)}](\text{esu}) = 10^{-2} \frac{\epsilon_0 c^2 n_0^2 \lambda}{4 \pi^2} \beta (\text{cm} / \text{W}) \quad (2)$$

where ϵ_0 is the permittivity of free space, c is the velocity of light in vacuum, and n_0 is the linear refractive index of the medium.

The nonlinear refractive index (n_2) of the medium is given by the relation [35]:

$$n_2 = \frac{\Delta\theta_0 \lambda}{2 \pi I_0 L_{\text{eff}}} \quad (3)$$

and the change in the refractive index (Δn) of the medium is given by the following relation [35, 38]:

$$\Delta n = n_2 I_0 \quad (4)$$

where λ is the laser wavelength and I_0 is the intensity of the laser beam at focus ($z = 0$), and given by:

$$I_0 = \frac{2 P_0}{\pi \omega_a^2} \quad (5)$$

where P_0 is the laser input power. L_{eff} is the effective length

of the sample and given by:

$$L_{\text{eff}} = (1 - \exp(-\alpha_0 L)) / \alpha_0 \quad (6)$$

where L is the true sample length and α_0 is the linear absorption coefficient. $\Delta\theta_0$ in Eq. (3) is the on - axis phase shift of the laser beam traversing the medium. This phase shift is related to the difference between the peak and valley transmittances (T_p and T_v) for the closed - aperture z - scan $\Delta T_{p-v} = T_p - T_v$ according to the following relation [33, 34]:

$$\Delta T_{p-v} = 0.406 (1 - S)^{0.25} |\Delta\theta_0| \quad (7)$$

where $|\Delta\theta_0|$ is the on - axis nonlinear phase shift at the focus and S is the linear transmittance of the aperture and given by:

$$S = 1 - \exp(-2 r_a^2 / \omega_a^2) \quad (8)$$

where r_a is the radius of the aperture and ω_a is the radius of the laser beam at the entrance of the aperture.

The nonlinear absorption coefficient (β) can be calculated from the open - aperture z - scan data and using the following relation:

$$\beta = \frac{2\sqrt{2}}{I_0 L_{\text{eff}}} \Delta T \quad (9)$$

where ΔT is the normalized transmittance difference between peak at the focal point ($z = 0$) in the open - aperture z - scan normalized transmittance curve and the baseline.

The absolute value of the third - order nonlinear optical susceptibility was calculated from the following relation:

$$|\chi^{(3)}| = [(\text{Re}(\chi^{(3)}))^2 + (\text{Im}(\chi^{(3)}))^2]^{1/2} \quad (10)$$

Figures 5, 6, 7, 8, and 9, respectively, illustrate the variations of ΔT_{p-v} , n_2 , Δn , β , and $|\chi^{(3)}|$ as a function of the Celestin Blue B dye concentration. It is clearly seen that the values of n_2 and β increase as the dye concentration increases. This may be attributed to the fact that, as the dye concentration increases the number of dye molecules increases and more particles are thermally gaited resulting in an enhanced effect. The calculated values of the ΔT_{p-v} , n_2 , Δn , β , and $|\chi^{(3)}|$ are listed in Table (1).

Table 1. The calculated values of the nonlinear optical parameters of Celestin Blue B dye - doped polymer film for five different dye concentrations.

Concentration (mM)	ΔT_{P-V}	$n_2 (\text{cm}^2/\text{W}) \times 10^{-7}$	$\Delta n \times 10^{-4}$	$\beta (\text{cm} / \text{W}) \times 10^{-3}$	$ \chi^{(3)} (\text{esu}) \times 10^{-6}$
0.05	0.91	- 0.65	- 2.32	- 0.16	1.66
0.06	1.13	- 0.81	- 2.89	- 0.19	2.07
0.07	1.36	- 0.98	- 3.47	- 0.23	2.49
0.08	1.54	- 1.12	- 3.97	- 0.26	2.85

Optical power limiting behavior of Celestin Blue B dye - doped polymer film at different dye concentrations was studied. The laser output power is plotted as a function of the laser input power for different dye concentrations, as shown in Figure 10. It is seen that the laser output power rises initially with increase in laser input power, but after a certain laser input power value, which is called the optical power limiting threshold (P_{th}) [39, 40], the medium (the sample) starts to exhibit self - defocusing effect, resulting in a larger part of laser beam cut off by the aperture. Consequently the transmitted beam recorded by the photo - detector D_2 remained approximately constant. The optical power limiting behavior is significantly affected by the variation of the dye concentration, the sample with low dye concentration shows a weak optical power limiting while the sample with high dye concentration exhibits strong optical power limiting.

Figure 10. Optical power limiting behavior (laser output power as a function of laser input power) for Celestin Blue B dye - doped polymer film at different concentrations.

Values of the optical power limiting threshold (P_{th}) were

estimated from Figure 10, for the Celestin Blue B dye - doped polymer film. Figure 11 illustrates the relation between the optical power limiting threshold (P_{th}) and the dye concentration. It is clearly evident that the optical power limiting threshold linearly decreases with increasing the dye concentration. This is due to the fact that the number of absorbing molecules increases with increasing the dye concentration which in turn lowers the optical power limiting threshold. We can deduce from the observed results that the dye concentration plays an important role in controlling the power limiting behavior. Also, the incident intense laser beam can significantly change the absorptive and refractive properties of the medium (the sample) resulting in a greatly reduced output intensity and therefore it is important to determine the magnitude of the medium nonlinearity to find the suitable conditions for the optical power limiting behavior.

Figure 11. Optical Power limiting threshold (P_{th}) of Celestin Blue B dye - doped polymer film as a function of dye concentration.

4. Conclusions

Pure poly (methylmethacrylate) (PMMA) polymer film and Celestin Blue B dye - doped polymer films at different concentrations were prepared using casting technique. The third - order nonlinear optical properties and optical power limiting behavior of Celestin Blue B dye - doped polymer films have been investigated. The optical parameters, ΔT_{p-v} , n_2 , Δn , β , and $|\chi^{(3)}|$ were measured using the z - scan technique with a continuous wave laser beam at wavelength 532 nm. The experimental results showed that Celestin Blue B dye - doped polymer film has a large third - order optical nonlinearities. The origin of the nonlinear effects is attributed to the thermal variation of refractive index of the medium. It is found that the optical power limiting depends on the dye concentration and possesses low optical power limiting threshold. From the results, the Celestin Blue B dye - doped polymer film is expected to be promising candidate for applications on nonlinear photonic devices and optical limiters.
