Abstract: Background: Hepatocellular carcinoma (HCC) is one of the most common cancers worldwide. It was believed that ablation for tumors close to large vessels should be avoided for the concern of major complications. Microwave ablation (MWA) seemed to be a better choice than radiofrequency ablation (RFA) in treating HCC close to large vessels (≥ 3 mm), for its advantages of a lower susceptibility to heat-sink effects (blood-vessel-mediated cooling), as well as the ability to achieve larger tumor volumes in shorter time. The aim of this study is to evaluate safety and efficacy of MWA for HCC close to large vessels. Methods: 32 patients with 52 HCC lesions were included, all patients have a lesion close to large vessel. 14 patients had single lesion, 16 had two lesions and 2 had three lesions. All patients are Child-Pugh A or B within Milan Criteria and class A disease Barcelona Clinic Liver Cancer (BCLC). Results: This study was conducted on 32 HCC patients 24 males and 8 females with median age 63 years. 32 HCC lesions were close to large vessel while 20 lesions were not close to large vessel. Laparoscopic assisted percutaneous MWA was decided as the treatment of choice for all patients. two patients (6%) had major complications (one patient had right portal vein thrombosis and the other patient had intra-hepatic hematoma), 3 patients (9%) had minor complications in the form of skin burn. Local tumor progression (LTP) occurred in 2 lesions (3.8% of lesions). Conclusion: laparoscopic assisted percutaneous MWA proved to be a safe and effective as a management for HCC close to large vessels.

Keywords: Laparoscopic Assisted Percutaneous, Microwave Ablation, Hepatocellular Carcinoma

1. Introduction

Hepatocellular carcinoma (HCC) is one of the most common cancers worldwide. [1] Egypt has a high incidence of HCC (around 21% of cirrhotic Egyptian patients). This may be attributed to high prevalence of HCV in Egypt. [2] HCC has poor prognosis due to high degree of malignancy, high recurrence rates and the impaired liver function

associated with the disease. Surgical resection is the optimal treatment for early HCC in patients with compensated cirrhosis but the majority of HCC patients are not candidates for surgical resection because of their poor hepatic functional reserve, advanced tumors, and because a tumor location close to major intrahepatic vessels and multi-focal tumors preclude a negative margin resection. [3] Thermal ablation therapies have been widely used for the local treatment of HCC. [4] It

was believed that ablation for tumors close to large vessels should be avoided for the concern of major complications. [5, 6] Microwave ablation is electromagnetic wave which is better than radiofrequency ablation (RFA) in treating HCC close to large vessels, for its advantages of a lower susceptibility to heat-sink effects (blood-vessel-mediated cooling) and its ability to achieve larger tumor volumes in shorter time. [7]

The aim of this study is to evaluate safety and efficacy of MWA of HCC close to large vessels.

2. Patients and Methods

This prospective study conducted in National Hepatology and Tropical Medicine Research Institute (NHTMRI), Cairo, Egypt from February 2014 to December 2018 on 32 patients (24 males and 8 females) with 52 HCC lesions. The median age of the patients was 63 years. All patients had lesion close to large vessel ≥ 3 mm diameter (hepatic vein, portal vein, inferior vena cava). 32 HCC lesions were close to large vessel while 20 lesions were not close to large vessel. 14 patients had single lesion, 16 had two lesions and 2 patients had three lesions as shown in (figure 1). The median tumor diameter was 2.4cm, 45 lesions were ≤ 3 cm and 7 lesions were > 3 cm these 7 lesions were close to large vessel. All patients had cirrhosis due to hepatitis C or B virus infection. They were within Milan Criteria and they were class A disease Barcelona Clinic Liver Cancer (BCLC). The diagnosis of HCC was based on American Association for the Study of Liver Diseases (AASLD) radiological criteria or histology. [8, 9] Four lesions of the 52 lesions were discovered intraoperative by intraoperative laparoscopic ultrasound. The nature of the procedure was explained and informed consents were taken from all participating patients. Description of patients and HCC lesions included in this study is summarized in (table 1).

Table 1. Description of patients and HCC lesions included in the study.

Number of patients	32
Median Age (years)	63
Male/female	24/8 patients
Within Milan criteria n (%)	32 (100%)
BCLC Stage A n (%)	32 (100%)
Liver cirrhosis n (%)	32 (100%)
Child – Pugh n (%)	
Class A	25 (78%)
Class B	7 (22%)
Class C	0 (0%)
Total number of HCC lesions n (%)	52 (100%)
HCC Close to large vessel n (%)	32 (62%)
HCC Not close to large vessel n (%)	20 (38%)
HCC lesions ≤ 3 cm n (%)	45 (87%)
HCC lesions >3 cm and < 5 cm n (%)	7 (13%)

2.1. Surgical Procedure

Procedures were performed under general anesthesia with the patient in a supine position. Pneumoperitoneum was induced and inflation pressure was maintained at 10-13 mmHg. A second trocar was inserted in the right or left upper quadrant

according to the site of liver lesions to allow the passage of the ultrasound probe. After the peritoneal cavity had been explored, laparoscopic intraoperative ultrasound (LIOUS) was performed to complete the disease staging, confirm the tumor location and establish its relationship with the major hepatic vasculature. MW ablation needles were inserted percutaneous and placed inside the lesion under laparoscopic intraoperative ultrasound (LIOUS) guidance as shown in (figure 2). Tumor ablation was confirmed in all patients during the procedure by LIOUS then a drain was inserted to be removed postoperatively. The mean operative time was 88 minutes and the median MW ablation time for each HCC lesion was 6 minutes (range 4-12 min).

2.2. Microwave Ablation (MWA)

Is electromagnetic energy, not electric current, no need for grounding pads. The devices consist of three basic parts: generator, flexible cable and antenna. In the absence of current flow, the electromagnetic field creates a rapid and homogeneous heating of tissue and subsequently coagulation necrosis. The best heating effect is achieved in tissues with a high content of water and the worst is observed in fat. [10] Another mechanism of MWA function is ionic polarization with conversion of kinetic energy into heat. A more homogeneous, larger ablation zone that is easily predicted is feasible and the heat-sink effect is attenuated. [11, 12] The faster heating and higher temperatures provided by microwave energy may be a reason for the reduced heat-sink effect. [13]

Microwave system used in our institution in this study is (AMICA- GEN Apparatus for microwave ablation system) with frequency of 2,450 MHz and generators capable of producing 140 Watts of power. AMICA™ Probe has Sharp trocar point for easy penetration into tissues. Very good US visibility. Internal water cooling to avoid shaft overheating. Built-in thermocouple for probe temperature monitoring. Embedded memory chip for probe identification by AMICA-GEN, providing enhanced ease and safety of use. This MWA system provides large and fast ablations: more than 4 cm in diameter in 10 minutes, with a single probe.

2.3. Postoperative Follow-up

The median hospital stay was 3 days. Abdomino-pelvic ultrasound was done for all patients before discharge from hospital. The local efficacy of ablation and local tumor progression was evaluated with tri-phasic CT and/or MRI and serum alpha fetoprotein in all patients after one month, every 3 months for the first year and every 6 months thereafter. Follow up period was at least 12 months. Local tumor progression (LTP) is defined as enhancement at the arterial phase with washout lesion at the delayed phase of the contrast-enhanced imaging examination (tri-phasic computed tomography and magnetic resonance imaging) inside or abutting the ablation zone during follow-up.

2.4. Statistical Analysis

Descriptive statistics were reported as frequencies and percents.

3. Results

In this study 32 patients with 52 HCC lesions underwent laparoscopic assisted percutaneous MWA. There were 14 patients (44%) had single lesion, 16 (50%) had two lesions and 2 patients (6%) had three lesions. The median tumor diameter was 2.4 cm, 45 lesions (87%) were ≤ 3 cm and 7 lesions (13%) were > 3 cm and < 5 cm. 32 HCC lesions (62%) were close to large vessel while 20 lesions (38%) were not close to large vessel as shown in (figure 3). The follow-up period was at least 12 months.

The median postoperative hospital stay was 3 days. There was no perioperative mortality. Technical success was 100%, no conversion to open surgery, all lesions were completely ablated as confirmed by LIOUS. According to SIR classification [14] system for complications by outcome two patients (6%) had major complications (one patient had right portal vein thrombosis and the other patient had intra-hepatic hematoma), these lesions were > 3 cm and close to large vessels. Patients with complications were treated conservatively with medical treatment and no surgical intervention was required. Minor complications occurred in 3 patients (9%) in the form of skin burn. Follow up period was at least 12 months with tri-phasic CT and/or MRI and serum alpha fetoprotein for all patients after one month, every 3 months for the first year and every 6 months thereafter (figure 4 show triphasic MRI before and after MWA). Local tumor progression (LTP) occurred in 2 lesions (3.8% of lesions) that were > 3 cm at 12 months follow up visit.

Number of patients with single, 2 and 3 HCC lesions

■ single lesion in 14 patients ■ 2 lesions in 16 patients ■ 3 lesions in 2 patients

4. Discussion

Thermal ablation currently represents the first-line treatment option for early stage unresectable HCC. Unresectable HCC includes single lesion in a deep location, multinodular disease in patients with deteriorated liver function. These procedures are usually performed by percutaneous approach but in particular conditions as in cases of nodules in "at-risk" location laparoscopic ablation is recommended. [15]

Microwave ablation is electromagnetic wave which is better than radiofrequency ablation (RFA) in treating HCC close to large vessels, for its advantages of a lower susceptibility to heat-sink effects and its ability to achieve larger tumor volumes in shorter time. [7] In MWA multiple antennae can be simultaneously activated without the electrical interference phenomena observed in RFA, thus allowing more rapid treatment of large or multifocal tumors. [16]

The aim of this study is to evaluate safety and efficacy of MWA of HCC close to large vessels.

In the current study we present single-center experience of laparoscopic assisted percutaneous MWA for HCC. There was no perioperative mortality. Technical success was 100%, no conversion to open surgery, all lesions were completely ablated these results are comparable to Simo et al 2011 but superior to results of 3 retrospective percutaneous

sonographically guided studies that reported complete ablation rates of 89%-94%, our results may be explained by the use of laparoscopic technique guided by LIOUS for complete ablation confirmation. [17-20]

As regard safety in the current study there was no perioperative mortality, 2 patients had major complications (6%) (one patient had right portal vein thrombosis and the

other patient had intra-hepatic hematoma) patients were treated conservatively with medical treatment and no surgical intervention was required. These results are comparable to the results of a large multicenter Italian study in which the major complication rate was 2.9% and the peri-procedural mortality rate < 0.01% after MWA for HCC. [21]

Figure 5. Show triphasic MRI before and after MWA.

1a: Dynamic MRI before ablation (arterial phase): well defined right lobe segment V HCC with homogenous arterial enhancement - 5mm from right portal vein branch.

1b: Dynamic MRI before ablation (portal phase): HCC showing early wash out.

1c: Dynamic MRI before ablation (venous phase): HCC shows characteristic wash out.

2a: Dynamic MRI after ablation (arterial phase): right lobe segment V non enhanced area denoting good ablation with no definite tumoral reactivity.

2b: Dynamic MRI after ablation (portal phase): the abated area still shows no enhancement with patent homogeneously enhanced right portal vein branch.

2c: Dynamic MRI after ablation (venous phase): still no enhancement at the ablation area denoting good ablation.

Portal veins thrombosis occurs more frequently than hepatic veins and should be treated cautiously during MWA, particularly in patients with liver cirrhosis. [22] The mechanism behind the increased rate of portal veins thrombosis compared with hepatic veins is related to differences in flow velocity, flow pattern, and total blood flow. Portal veins have slower blood flow because of drainage into high-resistance hepatic sinusoids. This relatively sluggish flow is exacerbated in patients with cirrhosis and portal hypertension, who have even higher sinus pressures and slower ante grade portal vein flow. [23] Slow flow is less effective at dissipating heat, resulting in vessel occlusion. [24]

In the current study local tumor progression (LTP) occurred in 2 lesions (2/52, 3.8% of lesions) that were >3 cm and close to large vessels at 12 months follow up visit. These results are comparable to Abdelaziz *et al.* with rate of 3.9% but superior to Chiang J, *et al.* 2016, Vogl *et al* and Zhang *et al* with recurrence rate of 9.6%, 8.3% and 10.5% respectively. [22, 25-27] All these last-mentioned studies reported lower recurrence rates when MWA was compared to RFA.

5. Conclusion

Laparoscopic assisted percutaneous MWA is safe and effective management for HCC close to large vessels. Combination of laparoscopic intraoperative ultrasound LIOUS with Laparoscopic assisted percutaneous MWA helps in accurate detection of tumor location, its relation to large vessels, helpful in confirmation of tumor ablation and can detect new HCC lesions not detected preoperatively with lower recurrence rates.
