Abstract: The distillers' grains fermentation was studied, which was from ethanol fermentation of sweet sorghum stalk. The factors such as temperature, concentration, inocula, pH etc. were analysis. The results showed the optimal temperature was 55°C, the optimal weight concentration of distillers' grains was 3.3%, the amount of inocula was 1.5%, and the pH should be adjusted before fermentation. Under this condition, the maximum biogas production was 3710mL/d and appeared in the 9th day. The overall length of the fermentation period was 32d, and the biogas production rate was up to 509mL/gTS. The results could provide a theoretical basis for the fermentation of biogas production from distillers' grains.

Keywords: Distillers' Grains, Biogas, Fermentation

1. Introduction

At present, 85% energy is obtained through non-renewable mineral resources in the world. Due to the limited reserves of mineral resources and the increasing awareness of environmental protection, people began to seek new alternative resources [1-4]. Processing non-grain bioethanol with sweet sorghum stalk has many benefits for people. For example it can avoid competing for food with humans, land with grain, profits with traditional industries, and resources with other countries [5, 6]. It has strategic significance to upgrade the future energy structure, ensure energy security and improve the living environment of human beings continuously [7]. However, it will produce a large number of distiller's grains with sweet sorghum stalk producing ethanol. If these distiller's grains are not stored properly or used in time, they are prone to mildew and deterioration, which not only waste valuable resources, but also seriously pollute the surrounding environment [8, 9].

Now China is short of energy, and the per capita natural gas resources is far lower than average level of the world [10-11]. If the distiller's grains came from bio-ethanol production are converted into renewable clean energy by biogas fermentation technology, it can solve the disposal problem of distiller grain in

million tons, and the biogas can be directly used as household gas or generated electricity or produced vehicle fuel or injects natural gas network by further purification. The biogas fermentation residue can also be produced to organic fertilizers, which plays an important role in environment and land improvement [12-14]. This paper mainly study the effects of temperature, TS concentration of feedstock, PH and inocula concentration on biogas fermentation of distiller's grains which produced from sweet sorghum stalk after ethanol production. It can provide some theoretical basis for related production enterprises to make full use of distiller's grains [15, 16].

2. Material and Method

2.1. Experiment Material

The residue of distiller's grains after solid state fermentation to produce ethanol with sweet sorghum straw as raw material are provided by Shandong Bori Bioenergy Co., Ltd.

Biogas liquid in biogas tank with corn straw as raw material for experiment at 48°C are supplied by Shandong Bori Bioenergy Co., Ltd.

The sodium hydroxide solution at 1M (mol) concentration was used to adjust the pH of the substrate. The properties of various materials are shown in Table 1.

Table 1. Basic properties of raw materials.

Material	TS%	VS%	C%	N%	C/N	organic matter %	fibrin%
distillers' grains	16.55	15.36	7.32	0.31	24	12.45	6.37
inoculums	7.20	3.34	1.6	0.22	7	2.76	-

TS: total solid content; VS: volatile solid.

2.2. Experiment Method

The conical bottle of 2000mL sealed by rubber plug [17] was used as biogas fermentation device, and the 1500mL gas collecting bottle and 2500mL beaker were used as gas collecting device.

The biogas fermentation was performed in Erlenmeyer flask which was closed with suitable rubber plug. The total volume and working volume of the bottles were 2000mL and 1500mL. The gas collecting device was composed of 1500mL gas collecting bottle and 2000mL beaker. The biogas volume was measured based on the downward displacement of water. The specific device is shown in the Figure 1.

Figure 1. Biogas fermentation device.

2.2.1. The Method of Temperatures' Influence on Biogas Fermentation of Distillers' Grains

In all of the three 2000mL conical bottles, 299g distiller's grains and 312mL inoculum were added respectively, and then the tap water was added to the 1500mL, and the mixture was stirred evenly, that is, the TS mass of the distiller's grains was 3.3% of the fermentation broth. The TS mass of the inoculum was 1.5% of the fermentation broth. Before fermentation, the pH of the fermentation broth was adjusted to about 8.5 with the NaOH solution of 1mol/L, and the three fermentation bottles were placed at room temperature 25°C and 38°C respectively. A comparative experiment of biogas fermentation was carried out in a shaking bed at high temperature 55°C. In each group, three groups of parallel experiments were made, and a blank experiment was carried out with the fermentation broth of only the inoculum and the tap water

2.2.2. The Method of Different Feedstock TS Influence on Biogas Fermentation

In the six 2000mL conical bottles, 227g / 272g / 299g / 317g / 317g / 317g / 363g / 453g distiller's grains were added respectively to 312mL inoculum, and then added tap water to 1500mL, the TS quality of the distiller's grains was 2.5%, 3.0%, 3.3%, 3.5%, 4.0%, 5.0%, respectively. The mass ratio of the TS of the inoculum to the quality of the fermentation

liquor is 1.5%.

Before fermentation, the fermentation broth pH in each fermentation bottle was adjusted to about 8.5 with the NaOH solution of 1mol/L. A comparative experiment of biogas fermentation was carried out in a shaking bed with high temperature of 55°C. Each group was performed in two replicates. All the digesters were placed in three constant-temperature shakers and blank experiments were done with fermentation broth with only inoculum and tap water.

2.2.3. The Method of Different Inocula Amount Influence on Biogas Fermentation of Distillers' Grains

There were five treatments in the experiment, and the inoculum concentrations in each treatment were respectively 0.5%, 1.0%, 1.5%, 2.0%, 2.5%. The TS concentration of distillers' grains was 3.3%. The fermentation temperature was 55°C. The pH of liquid was adjusted to about 8.5 by sodium hydroxide solution at 1M (mol) concentration. The fermentation experiment were carried out in shaking table. Each treatment was arranged two parallel experiments. A blank experiment was carried out with the fermentation broth containing only inoculum and tap water.

2.2.4. The Method for Influence of Different pH on Biogas Fermentation of Distillers' Grains

There were two groups in the experiment. The inoculum concentrations in each group were 1.5% and the TS concentrations of the feedstock were 3.3%. The pH of one group was adjusted to about 8.5 by sodium hydroxide solution at 1M (mol) concentration. The other one remained the original pH. The fermentation temperature was 55°C. Each group was performed in two replicates. All the digesters were placed in three constant-temperature shakers and a blank experiment was done with only inoculum and tap water.

2.3. Analytical Methods

Daily biogas production and cumulative biogas production were obtained by downward displacement of water. The composition of the biogas was determined with a gas chromatography (GC1120). The total solid (TS) and volatile solid (VS) were determined according to standard methods. Total carbon was measured by potassium dichromate method, total nitrogen was measured by Kjeldahl method. the contents of hemicellulose, cellulose and lignin were determined with an automatic fiber analyzer. The biogas production period was calculated at 95% of the total biogas production and the pH value was determined with a precision pH acidity meter.

3. Results and Discussion

3.1. Effect of Temperature on Biogas Fermentation of Distillers' Grains

Figure 2. Daily biogas yield of different temperature.

Figure 3. Cumulative biogas yield of different temperature.

Figure 2 and Figure 3 are daily biogas yield chart and cumulative biogas production chart of distillers' grains at three temperatures. The results showed that on the first day of fermentation, the distillers' grains all entered the biogas production stage of the three groups. It may be related to the process of ethanol production. The distillers' grains had went through a preliminary fermentation during the process of ethanol production. In this process, the encapsulation of cellulose, hemicellulose and lignin in the distiller's grains was decomposed initially, and produced more easily degradable components and small molecular substances such as carbohydrates, organic acids and alcohols. The C/N rate of distillers grains is 24 which is in the best C/N rate range at biogas producing [18]. The maximum daily biogas yield of distiller's grains reached 3710 mL/d on the ninth day and the biogas production period was 32 days under the temperature of 55°C. The maximum daily biogas yield of distiller's grains reached 1760 mL/d on the nineteenth day and the biogas production period was 39 days under the temperature of 38°C. The maximum daily biogas yield of distiller's grains reached 1330 mL/d on the twenty-sixth day and the biogas production

period was 42 days under the temperature of 25°C. According to the above datas the peak time and the biogas production period of distillers' grains are shortened with the increasing of temperature. The main reason is that high temperature can accelerate the degradation of lignocellulose. The anaerobic fermentation speed of distiller's grains is fast [10-13]. According to the daily biogas yield chart, with the process of fermentation there were several small peaks of daily biogas production at three fermentation temperatures. It is because that the distiller's grains contain ethanol, amino acids, protein and other components, The time of the hydrolysis, acidification and biogas production of the components are different at the fermentation process. And they have stages, so there are many biogas production peaks [19].

According to the cumulative biogas production data, It can be seen that the cumulative biogas yield of distiller's grains is 25200 mL and the biogas yield of TS is as high as 509 mL/g under the temperature of 55°C. The cumulative biogas yield of distiller's grains is 21400 mL and the biogas yield of TS is as high as 432 mL/g under the temperature of 38°C. The cumulative biogas yield of distiller's grains is 19160 mL and the biogas yield of TS is as high as 387 mL/g under the temperature of 25°C. From above dates It can be seen that with the increase of temperature the cumulative biogas yield and the TS biogas yield of distillers grains are increased. This is because the higher the temperature, the more cellulose is degraded, the more raw materials are available to the microorganism, and the more biogas is produced [20-22]. Therefore, the optimum temperature is 55°C at producing biogas about distiller's grains fermentation. The reason why the experiment selected to ferment distillers' grains at high temperature is because the temperature of distiller's grains is higher after distilling and there is a certain amount of heat during the solid-state fermentation of alcohol in the early stage of distiller's grains. If the distiller's grains are directly fermented for biogas after coming out of the distillation tower, This part of the heat can be used to save energy.

3.2. Effect of Different TS Concentrations of Feedstock on Biogas Fermentation of Distillers' Grains

Figure 4. Daily biogas yield of different TS concentrations.

Figure 5. Cumulative biogas yield of different TS concentrations.

Figure 4 and Figure 5 are daily biogas yield chart and cumulative biogas production chart under different TS concentrations of distillers' grains. From the charts it showed that the fermentation entered the biogas production stage on the first day when the TS concentration of distillers grains ranged from 2.5% to 3.3%. The maximum daily biogas yield reached 1300 mL/d on the 13th day, the cumulative biogas yield was 16750mL, and the biogas yield of TS was 447mL/g when the concentration of TS in distiller's grains was 2.5%. The maximum daily biogas yield reached 1900 mL/d on the 11th day, the cumulative biogas production was 19940mL, and the biogas yield of TS was 443mL/g at 3.0% TS concentration. The maximum daily biogas yield reached 3710 mL/d on the 9th day, the cumulative biogas production was 25200mL, and the biogas yield of TS was 509mL/g at 3.3% TS concentration. The results show that the cumulative biogas production and raw material biogas yield gradually increase with the increasing TS concentration of the feedstock when the TS concentration of distiller's grains ranges from 2.5% to 3.3%. This is because when the TS concentration of distiller's grains is too low, the amount of organic matter in unit volume is less and the food of the methanogenic bacteria is less. So in a certain range, with the increase of TS concentration of distiller's grains, the cumulative biogas production will increase [23].

When the TS concentration of feedstock ranged from 3.3% to 5%, the time for the fermentation entering the biogas production stage was longer. The maximum daily biogas yield reached 3900 mL/d on the 9th day, the cumulative biogas yield was 25430mL, and the biogas yield of TS was 484mL/g at 3.5% TS concentration. The maximum daily biogas yield reached 1030 mL/d on the 16th day, the cumulative biogas production was 26810mL, and the biogas yield of TS was 447mL/g at 4% TS concentration. The maximum daily biogas yield reached 1500 mL/d on the 21th day, the cumulative biogas production was 26640mL, and the biogas yield of TS was 335mL/g at 5% TS concentration. As it shows the peak time of biogas production of different treatments delay gradually with the increasing of TS concentration. The cumulative biogas production increases slowly and the biogas yield of raw

materials decreases gradually, when the TS concentration of distiller's grains is higher than 3.3%. It is because when the TS concentration of the feedstock is too high, the rate of acidification exceeds the methane fermentation rate, which is easy to cause the acidification risk to inhibit the activity of methanogens, thereby affecting the biogas production amount [24-25].

According to the above analyses the best TS concentration for biogas fermentation of distiller's grains is 3.3% at 55°C, which is lower than that of straw [16, 18]. It may be that some enzymes, yeasts and other substances enter the distiller's grains during the early fermentation of ethanol, which increases the concentration of degradable components in the distiller's grains, so the effective TS content of the final distiller's grains is higher than other materials [14].

3.3. Effect of Inoculums Amount on Biogas Fermentation of Distillers' Grains

Figure 6. Daily biogas yield of different inoculums amount.

Figure 7. Cumulative biogas yield of different inoculums amount.

Figure 6 and Figure 7 are daily biogas yield chart and cumulative biogas yield chart of distillers' grains at different inoculation amount. From the charts it can be seen that the maximum daily biogas yield reached 1010 mL/d on the 21th day, the cumulative biogas yield was 20060mL when the amount of inoculums was 0.5%. When the amount of

inoculums was 1.0% the maximum daily biogas yield reached 20700 mL/d on the 16th day, the cumulative biogas yield was 22370mL. The maximum daily biogas yield reached 3710 mL/d on the 9th day, the cumulative biogas yield was 25200mL when the amount of inoculums was 1.5%. The results show that the time of the maximum daily biogas yield of distiller's grains is gradually shortened and the cumulative biogas production is gradually added with the increasing of inoculation amount when the amount of inoculums is from 0.5% to 1.5%. This is because when the inoculation amount is small, the methane bacteria content in the digesters is relatively small, which requires a enrichment process of methanogenic bacteria. So with the increase of inoculation amount, the peak time of biogas production rate is gradually shortened. At this time, the cumulative gas production of distiller's grains is mainly determined by the quantity of methanogenic bacteria, so the cumulative gas production increases gradually with the increase of inoculation amount [16, 19].

When the inoculums amount was from 1.5% to 2.5%, the daily biogas yield of distiller's grains all reached the maximum at about 9 days, which were 3710 mL, 3310 mL and 3340 mL respectively. The cumulative biogas yield was 25200 mL, 25430 mL and 25570 mL. It can be seen that when the inoculums amount exceed 1.5%, the maximum daily biogas yield of distiller's grains was no longer advanced, the increase of cumulative biogas production became slow. This is due to the fact that when the inoculums amount reaches a certain value, the enrichment process of methanogenic bacteria is no longer required so the time of the maximum daily biogas yield is basically the same. At this time, the cumulative biogas production is mainly determined by the total amount of organic matter in distiller's grains rather than the amount of methanogenic bacteria [26-28].

In conclusion, the optimum inoculums amount of distiller's grains for biogas fermentation at high temperature was 1.5%. Under this condition it could save inoculums, and the rate of fermentation and cumulative biogas production all reached the best state.

3.4. Effect of Different pH Value on Biogas Fermentation of Distillers' Grains

Figure 8 and Figure 9 show the daily biogas production and cumulative biogas production of distiller's grains in two groups of contrastive tests respectively. The figure is observed that if the pH value of the fermentation is not adjusted, it would drop rapidly from 7.02 to 4.5 on the third day and remain 4.5 until the fifteenth day of fermentation. The average daily biogas yield is only about 200 mL at this stage. the peak of daily biogas yield appears on the 16th day, It is 1220 mL/d. The cumulative biogas production is 24930 mL, and the biogas production period is 51 days. It is because that the distiller's grains goes through initial fermentation process during ethanol fermentation. In the initial stage of biogas fermentation, the distiller's grains hydrolyzes rapidly and produces a large number of volatile fat acids and carbon dioxide. The dissolution of volatile fat acids and part of carbon dioxide in the liquid make the pH value of the fermentation

system to drop and acidify.

If the pH value of the feedstock is adjusted to about 8.5 with sodium hydroxide solution of 1 mol/L before fermentation, the feedstock rapidly enters the normal biogas production stage, and the acidification stage only lasts about 3 days. The maximum daily biogas yield is 3710mL/d at 9th days. The cumulative biogas production is 25200 mL and the biogas production period is 32 days. The main reason is that alkaline substances ionize OH⁻ when alkaline substance is added into the liquid before fermentation, which neutralize a part of acid and make the fermentation broth rapidly enter the methanogenesis stage.

Figure 8. Daily biogas yield of two treatments.

Figure 9. Cumulative biogas production of two treatments.

4. Conclusion

The biogas fermentation with distiller's grains as raw materials saves the pretreatment process of raw materials. Among them, carbohydrates, alcohols, organic acids and other easily degradable components and small molecular substances are high. The C/N ratio of distiller's grains is about 25, which is the best C/N ratio for biogas fermentation. It doesn't need to add nitrogen-containing substances such as urea to adjust, which not only reduces the cost, but also accelerates the startup speed of fermentation.

The distiller's grains have a certain amount of heat when

they come out from the distillation tower. The high temperature biogas fermentation method can make full use of this part of the heat of distiller's grains, thus saving energy consumption and increasing the amount of biogas production and shortening the period of gas production.

The distiller's grains contain some enzymes, yeasts and other substances, which increased the effective fermentation components of distiller's grains. Therefore, the optimal TS concentration for biogas fermentation of distiller's grains at high temperature was 3.3%, which is lower than that of straw.

The acidification stage of distiller's grains can be shortened by adjusting the pH value of the feedstock before fermentation, and the methane production stage can be quickly entered.

The optimal temperature was 55°C, the best concentration of distillers' grains was 3.3%, the optimal amount of inocula was 1.5%, and the pH value should be adjusted before fermentation. Under this condition, the maximum daily biogas production was 3710mL/d and appeared on the 9th day. The overall length of the fermentation period was 32d, and the TS biogas yield was up to 509mL/gTS.
