Vol. 4, No. 2, 2016, pp. 12-21. doi: 10.11648/j.sjac.20160402.11

Abstract: The South Region of Pemba is one of the two Regions in Pemba Island. Residents within the region depend on groundwater as the main water source for the domestic and other social purposes. This study was conducted to assess the quality of drinking water in different areas of South region of Pemba. In order to evaluate the quality of groundwater in the study area, 17 groundwater samples were collected and analyzed for different physico-chemical parameters. In each water sample, four physicochemical parameters were analyzed, namely, electrical conductivity (EC), total dissolved solids (TDS), pH, and turbidity. For the case of metals, eleven metals, namely, Cd, Co, Cu, Cr (III), Li, Fe, Mg, Ni, Pb, Sr, and Zn were analyzed using standard procedures. The data obtained were then compared with the available WHO and or USEPA drinking water standards. All the samples had EC and TDS within the recommended limits, while 53% and 29% of the samples had higher turbidity levels and lower pH, respectively than the WHO recommended guidelines. All the samples contained Co, Cu, Fe, Mg, Ni, Pb, and Zn within the maximum admissible limits. According to heavy metal pollution index (HPI), degree of contamination (Cd), and heavy metal evaluation index (HEI), only one area (Mgonanje-1) showed alarming risks. In most water samples, the ratio of concentrations of Li to Ni was greater than 1, while all Sr to Mg ratios were less than 1. Generally, the values of the analyzed physico-chemical parameters were within the recommended maximum admissible limits. However, the study recommends the stakeholders and other responsible authorities to take appropriate and corrective measures for the water sources located at the Mgonanje area.

Keywords: Mgonanje, Alarming Risks, Li/Ni Ratio, Sr/Mg Ratio, HPI, HEI, Pemba Island

1. Introduction

The significance of water quality in human health and welfare attracts a great deal of interest and attention in the world. Access to adequate and safe water is essential for human survival, and is one among the fundamental human rights. Concerning public health, limited access to safe water undermines other public sectors such as public health, for instance communicable diseases. The provision of potable drinking water has been given priority in all national and international working documents.

Groundwater is a precious natural resource that is essential and fundamental for human health, socio-economic development, and functioning of ecosystems [1, 2]. Water supply sector plays a major role directly or indirectly to the

economy growth and social well being. The inadequate access to clean water is directly linked with the lack of basic sanitation [3]. Nevertheless, ground water can be polluted through contaminants originating from both natural and anthropogenic sources; and once water source is polluted, process to revamp the situation becomes very difficult [4]. The quality of groundwater is affected by natural and anthropogenic activities or factors. Numerous types of human activities including residential, municipal, commercial, industrial, and agricultural activities can all affect groundwater quality [5].

It is estimated that about 1.1 billion people globally drink unsafe water and the vast majority of diarrheal disease in the

world (88%) is attributable to unsafe water, sanitation and hygiene [6]. Microbial contamination is the most widespread form of groundwater contamination. It carries major health risks especially in developing world [7]. The quality of water is a crucial concern for humankind and development, since it is directly linked with human welfare [8].

Underground aquifers are the main source of domestic water in Zanzibar, but the quality of the water sources in different areas is at alarming risk due to deteriorating environmental conditions [9, 10]. In Pemba Island, large portion of the population is dependent on groundwater as a major source of water supply to meet domestic and other social purposes. Most of the water sources are hand-dug wells, and they form the major sources of portable water to nearby villages. Some of the wells are located within the vicinity of town municipality, while other sources are in remote areas.

Anthropogenic release of pollutants to the ground is a potential source of groundwater contamination. This is because; pollutants released to the ground find their way down to the soil profiles into the groundwater aquifers. Such type of contamination is very common in water sources located within unplanned settlements, which are characterized with dense population and poor or no sanitation facilities.

The levels of heavy metals and toxic contaminants either in their organic or inorganic form, have been continuously increasing in various areas of world [11]. Low recharge rate coupled with over-exploitation of groundwater, hydro-geochemical characteristics of the area can result in shaping more pollutants infiltration and rapid deterioration of water quality.

Furthermore, it is documented that the polluted water affects the human health, soil nutrients, livestock, biomass and environment in certain areas [12]. The infiltrations of noxious impurities from various sources such as municipal sewerage, agricultural and domestic effluents are among the key factors, which cause the deterioration of portable water quality [13].

When some metals are present in human body at certain dose, they can cause detrimental health effects. As an example, lead (Pb), when ingested at a certain level can lead to human health consequences, such as, vomiting, loss of appetite, anemia, intestinal colic, headaches, double vision, mental disturbance, anxiety, convulsions, coma, muscular weakness, loss of memory, and damage of brain, liver and kidney [14]. Cadmium (Cd) is a non-essential element for living organisms and has very high mobility in soil-plant systems, with tendency to adversely affect both human health and the functioning of ecosystems [15]. While the shortage of iron causes disease called "anemia" and extended consumption of drinking water with high concentration of iron may lead to liver disease called as haemosiderosis [16].

Other metals such as; Mn, As, Ti, Cr, V, Co, Cu, Fe, Ni, and Zn and their compounds have been found to be initiators

or promoters of carcinogenic activity in animals. Furthermore, Al, Hg, Be, Sb, Ni, Co and Cd can cause adverse reproductive/fertility problems [17].

There are few studies on status of water quality in Zanzibar, and majority of them give strong emphasis on microbial contamination, while physico-chemical contamination seems to be of little attention. This trend is based on the logic that microbial contamination has acute responses as compared to other categories. However, physico-chemical contamination is of equal importance, and its consequences can be linked to non-communicable diseases such as cancer. Recent studies on physico-chemical contamination carried out in Urban West Region of Zanzibar Island have indicated that large proportion of water samples contain various chemical species and some of which have carcinogenic effects [9, 10].

Natural groundwater contaminants and other unwanted constituents or impurities, can reach such a level that is detrimental for human life. Types, abundances, and concentrations of natural occurring impurities depend on the geological and hydrological conditions of the area. Nevertheless, soil microbial activities, the amount of falling precipitation and its pH can play significant role on the transport and fate of contaminants in to groundwater via different soil zones. As recharge water moves down the soil profile it may pick up a wide range of chemical species, such as magnesium, calcium, and chlorides. Thus, quality of the recharge water may also be subjected to considerable variations.

The purpose of this study is to assess the quality of groundwater sources used in South Region of Pemba Island with respect to selected physico-chemical parameters. An estimate was done for the risk potential due to metal pollution in analyzed groundwater. Three indices namely heavy metal pollution index (HPI), hazard index (HI), and degree of contamination index (C_d) were taken into consideration in estimating the metal pollution in groundwater.

2. Materials and Methods

In this study, water samples were collected from community water sources in the South region of Pemba Island. The collection of water samples was made in November, 2014, whereby a total of seventeen water samples were collected in different wells. The positions of the wells were marked using Global Positioning System (GPS) as presented in figure 1. The samples were collected in pre-cleaned polyethylene bottles that were rinsed with the water sample of the particular location. Before analysis, the samples were subsequently stored at 4°C for short a time as possible to minimize changes of the physicochemical characteristics of the metals [18].

The collected samples were then transported and stored in laboratory for analysis. Handling of the samples at different stages was in accordance with the protocol given in the standard EPA method 200.7.

Figure 1. Location of the sampling areas in South Region of Pemba Island.

2.1. Analysis of the Samples

The pH, EC, turbidity and TDS were measured in situ using Hach multi-parameter water quality meter Model U-53G. An Inductively Coupled Plasma Optical Emission Spectroscopy (ICP-OES, Thermo Scientific iCAP 6000) method was used to determine concentrations of eleven metals which are, cadmium, lithium, strontium, magnesium, cobalt, nickel, lead, iron, chromium, zinc, and copper. Before the metal analysis, ICP-OES was calibrated using standard manufactured stock solution.

2.2. Reagents

All the chemicals used for the analytical determination were ultrapure compounds. Water for standard preparations was ultrapure water from Fisher/Barnstead with resistivity of 17.9 – 18.3 MΩ-cm. The standard multi-elements stock solutions were purchased from Inorganic Ventures, Merck (Darmstadt, Germany). The standard multi-elements stock solutions containing 1000 ppm, and the elements contained are such as; Cu, Ni, Pb, Na, Ca, As, Li, Mg, Mn, Sr, and Mn.

2.3. Data Analysis

Descriptive statistics including univariate and multivariate statistical methods of analysis were also used in the study. The software SPSS 16.0 was used for statistical analysis. The correlation-matrix, which is based on the Pearson's correlation coefficient, was utilized for displaying relationships between variables.

2.4. Pollution Evaluation Indices

Nature of the examined parameters was selected based on, firstly, the consequences of the anthropogenic activities, agriculture in particular, and secondly, the location of the water sources (up the hill or down the hill). In general, pollution indices are applied to give an estimate of the quality of the water under consideration. In this study, heavy metal pollution index (HPI), heavy metal evaluation index (HEI) and the degree of contamination (C_d) were calculated for each water sample (Eq. 1-5). The values of these indices are presented on Figure A2.

The HPI and HEI methods provide an overall quality of the water with respect to heavy metals. The C_d method, gives an estimate of the quality of water with respect to the degree of contamination using contamination factor. Therefore, the C_d recapitulates the combined effects of a number of quality parameters regarded as unsafe to domestic water [19].

The indices evaluated in this study are; heavy metal pollution index (HPI) as proposed by [20]. C_d also known as contamination index, which was developed by [21]. C_d is also used as reference for estimating the extent of metal pollution [22]. Degree of contamination is classified in to three categories, namely, low ($C_d < 1$), medium ($C_d = 1-3$), and high ($C_d > 1$) [23]. Heavy metal evaluation index (HEI) depicts an overall quality of the water with respect to heavy

metals [23].

$$HPI = \sum_{i=1}^n WiQi / \sum_{i=1}^n Wi \quad (1)$$

Where: W_i and Q_i are unit weight and the sub-index of the i^{th} parameter, respectively, and n is the number of parameters considered. The sub-index (Q_i) is calculated according to Eq. (2).

$$Q_i = \sum_{i=1}^n \frac{|M_i - I_i|}{S_i - I_i} \times 100 \quad (2)$$

$$HEI = \sum_{i=1}^n \frac{H_c}{H_{mac}} \quad (3)$$

Where: H_c and H_{mac} are monitored and maximum admissible concentration respectively.

$$C_d = \sum_{i=1}^n C_{fi} \quad (4)$$

C_{fi} is a subindex, which shows contamination factor and is calculated according to Eq. (5)

$$C_{fi} = \frac{CM_i}{CS_i} - 1 \quad (5)$$

C_{fi} , CM_i , and CS_i , are the contamination factor, analytical value, and upper permissible concentration for i^{th} component respectively, while n denotes the 'normative value'.

3. Results and Discussion

The results on metal concentration and other physico-chemical parameters are summarized in Table 1.

Table 1. Descriptive statistics showing the concentrations of the analyzed parameters.

Parameter	Unit	Min. Level	Max. Level	Site with Max. Level	MAL	Area with max. detected concentration
Cd	mgL ⁻¹	< DL	31	14	0.003 ^a	Mgonanje1

Turbidity	NTU	1.16	25.6	14	5 ^a	Mgonanje1

^aand ^b is according to WHO and USEPA drinking water standards respectively

DL: Detection Limit; MAL: Maximum Admissible Level

Descriptive statistics showing the levels or concentration of the analyzed parameters in water samples are presented in Table-1. The minimum concentrations of some metals are

assigned with the mark < DL, indicating the concentrations were below the detection limit of the ICP-OES. All the raw data are depicted on Figure A1.

3.1. Correlation Between Physico-chemical Parameters in the Water Samples

The correlation among the behavior of analyzed

parameters in water samples are expressed by Pearson coefficient. While parameters were observed to have positive correlation, for instance zinc and copper, others correlate negatively for example lead (Pb) and chromium III (Table 2).

Table 2. Correlation between Physico-chemical parameters in the water samples.

Correlation Matrix												
Parameters	Cd	Co	Cr	Cu	Li	Mg	Pb	Sr	Zn	EC	pH	TDS

3.2. Levels of pH, EC, TDS and Turbidity in Water Samples

The values of pH, EC, TDS, turbidity, as well as metal concentrations are noticeable in Tables 1. The water pH ranged from 6.47 to 7.27, while the values of EC, TDS, and turbidity (Fig. 3) were evaluated to be 166 to 673 $\mu\text{S}/\text{cm}$, 108

to 431 mg/L^{-1} , 1.16 to 25.6 NTU respectively. The sample areas with maximum levels of the analyzed parameters are marked in Table 1. Strong correlation ($r^2 = 0.999$) was shown between TDS and EC (Fig. 2). The highest level of TDS correlates positively with the highest level of EC (Table 1).

Figure 2. EC-TDS correlation in water samples.

Figure 3. Turbidity levels in water samples.

3.3. Concentrations of Cr (III), Li, and Sr in Water Samples

The concentrations of Cr (III), Li, and Sr in water samples were in the range of: < DL to 0.0346, 0.0162 to 0.0622, and 0.0161 to 0.2543 mgL⁻¹ respectively (Table-1, Figure 4). As shown on the Figure A1, for 94% of water samples, lithium to nickel ratios were greater than 1, suggesting relatively higher levels of lithium in analyzed water sources as compared to levels of nickel. In all water samples, strontium to magnesium ratios were less than 1, indicating that

strontium is in relatively at higher concentrations in water sources compared to magnesium.

Strontium showed relatively strong correlation with other metals, such as; Mg, Ni, and Pb, with Pearson correlation coefficients of 0.628, 0.857, 0.861 respectively (Table 2). The strong positive correlation coefficients among analyzed metals may indicate similarities in their physical and chemical properties, and possibly, these metals might originate from common source.

Figure 4. Concentrations of Cr (III), Li, and Sr in water samples.

3.4. Concentrations of Fe and Pb in Water Samples

The levels of iron (Fe) and lead (Pb) in the samples were in the range of < DL to 0.0057, and < DL to 0.0097 mgL⁻¹ respectively. The highest levels of these parameters were

found at Mgonaje1 area (Table 1, Figure 5). Anthropogenic activities are suggested sources for elevated levels of lead and iron at Mgonanje area.

Figure 5. Concentrations of Fe and Pb in water samples.

3.5. Concentrations of Cu and Zn in Water Samples

The concentrations of copper and zinc ranged from < DL to 0.0612, and < DL to 0.069 mgL⁻¹ respectively. The maximum levels of copper and zinc were found at Afrikana sampling site (Table 1, Figure 6). Anthropogenic activities,

such as the application of fertilizers in agricultural activities are suggested to be the key sources for elevated levels copper and zinc in this area. Copper showed strong correlation with zinc ($r = 0.845$, Table 2).

Figure 6. Concentrations of Cu and Zn in water samples.

3.6. Concentrations of Cd and Ni in Water Samples

The levels of cadmium (Cd) and Nickel (Ni) in the samples were in the range of < DL to 31, and <0.0029 to 10.11 mgL⁻¹ respectively. The highest levels of the cadmium and nickel were found at Mgonanje1 area (Table 1,

Figure 7). The difference in levels of the analyzed parameters are affected largely by factors such as polluted domestic effluents, onsite septic tanks, the mixing of seawater and freshwater, and heavy metal containing fertilizer applications [9].

Figure 7. Concentration of Cd and Nickel in water samples.

The concentrations of copper and zinc ranged from 1.2 to 12.3 mgL⁻¹. The highest concentration was obtained at Mgonanje1 area (Table 1, Figure 8)

Figure 8. Concentration of Mg in water samples.

4. Conclusion

The data obtained from the present study reveals that, in comparison to the WHO and or USEPA drinking water standards, all the samples had EC, and TDS within the recommended limits. Greater than fifty percent of the samples had turbidity higher than the WHO recommended values, while greater than quarter of the samples had pH levels less than the minimum recommended pH limit. All the samples contained Co, Cu, Fe, Mg, Ni, Pb, and Zn within the maximum admissible limit. However, water sample from Mgonanje-1 had remarkably higher levels of all the three indices, HPI, C_d and HI. The observed elevated indices at Mgonanje area are suggested to be associated with the use of heavy metal containing fertilizers. This provides an indication of pollution hazards, and absence or weak drinking water treatment practices in the areas, which in turn have vital human health implications. With this regard, the study recommends the stakeholders and other responsible authorities to take appropriate and corrective measures for the water sources, specifically those allocated at Mgonanje and Afrikana. There is a strong demand of introducing relevant drinking water treatment techniques, which can reduce the

current levels of contaminants. Prevent any kind of waste disposal near groundwater sources that serve water for domestic and other purposes. Further study should be conducted on other physical, chemical, and biological parameters of significant health concern, and on identification of potential sources of the contaminants. Even though in other areas the values of these three indices are totally below the critical values, yet severe precautions must be given a great consideration because most of the water sources are located down the hills, and or near the paddy fields.

Acknowledgments

The authors of this manuscript would like to express thanks to His Majesty Government of Brunei Darussalam for funding this project, the State University of Zanzibar for permission for study leave. Special thanks to the staff of the faculty of Science of University Brunei Darussalam for their assistance. To mention few are, Hjh Faridah, Azzlin, Hjh Rasiah, Hj Jamil, Najib, and other UBD chemistry laboratory staffs for providing the necessary facilities and technical support they offer for the successful completion of the project.
