Abstract: This paper presents the effect of ambient meteorological parameters on the performance of different photovoltaic (PV) technologies based on PVSyst thermal model. The PV technologies considered are: monocrystalline silicon, polycrystalline silicon, amorphous silicon, microcrystalline and cadmium telluride. The study is conducted with hourly meteorological data obtained from PVSyst software meteo-file for Dakar in Senegal, with site coordinate of 14.5° N and 17.0° W. The results show that the different PV technologies have the same cell temperature because PVSyst uses default adsorption coefficient of 0.9 for the different PV technologies. However, the performance of the different PV technologies in response to the cell temperature differs in respect of their thermal coefficient. Among the five PV technologies studied, amorphous silicon has the lowest thermal coefficient and the best thermal response but the worst solar energy conversion efficiency. This means that amorphous silicon would occupy much more space to achieve the same energy output as the other PV technologies studied. Conversely, polycrystalline silicon has the highest thermal coefficient and the worst thermal response but its solar energy conversion efficiency is relatively higher than those of other PV technologies except monocrystalline silicon. The polycrystalline silicon with the same PV module size will yield more energy than its equivalent sized amorphous silicon PV module.

Keywords: Renewable Energy, Photovoltaic, Solar Radiation, Cell Temperature, Thermal Loss, Thermal Loss Model, PVSyst, Thermal Coefficient, Cell Efficiency

1. Introduction

As the quest for renewable energy increases, PV power systems continue to be one of the dominant choices. However, the suitability of a PV module technology for a particular site depends on some factors that include solar radiation distribution, annual temperature distribution, module temperature coefficient and variations in wind speed [1, 2, 3]. PV module temperature coefficient indicates the level of degradation of the output power of a PV module. Particularly, the electrical conversion efficiency of a PV module depends on cell temperature and this reduces as the cell temperature increases [1, 4]. The conversion efficiency here refers to the amount of solar energy reaching the PV module and the amount of that energy that can actually be converted to

electricity. The cell temperature depends on ambient temperature, solar irradiance, wind speed and module temperature coefficient. All the factors affecting the operation of a PV module are usually taken into account when determining their performance rating, therefore, manufacturers of PV modules usually provide PV ratings based on Standard Testing Conditions (STC). STC assumes an irradiance of 1000 W/m², solar spectrum of air mass of 1.5 and module temperature at 25°C [1]. However, PV modules deployed in the field operate over a wide range of environmental conditions and several models have been developed to determine the performance of PV modules under real life conditions. Such models effectively relate the PV cell temperature, PV cell efficiency, PV cell power output and thermal loss to the ambient temperature, wind speed and solar

irradiance. This paper therefore presents the impact of variation in temperature, wind speed and solar irradiance on the performance of PV modules based on PVSyst thermal model. The thermal model effectively relates the PV cell temperature, PV cell efficiency, PV cell power output and thermal loss to the ambient temperature, wind speed and solar irradiance. Apart from climatic and solar radiation parameters, there are PV technology dependent parameters that also affect PV output and this paper uses the PVSyst thermal model to compare the impact of the ambient climatic and solar radiation parameters on different PV technologies. The comparison is done in terms of operating cell efficiency, output power, thermal loss and drop in cell efficiency and is carried out on selected PV technologies under the same type of environmental conditions.

2. Theoretical Background

Photovoltaic cells are constructed from a variety of semiconductor materials such as silicon, cadmium sulphide, copper sulphide and gallium arsenide, and these cells directly convert solar radiation into electricity. Solar radiation contains photons, which when absorbed by the valence electrons of a PV cell, increases the energy level of such electrons. This causes the electrons to jump from the valence band into the conduction band and as long as a solar cell stays illuminated, the energized electrons are able to flow freely when connected in a circuit [5]. The relationship between the energy in a photon, E_{ph} and the wavelength of light, λ is given by

$$E_{ph} = \frac{hc}{\lambda}, \quad (1)$$

where h is Planck's constant and has the value of $6.625 \times 10^{-34} \text{ J/s}$, and C is the speed of light. For a cell made from silicon, which has a band gap of 1.11 eV , equation (1) reveals that only photons with a wavelength less than $1.12 \mu\text{m}$ can liberate electrons and thus generate electricity. The majority of solar energy that reaches the earth have wavelengths ranging from $0.2 \mu\text{m}$ to $1.2 \mu\text{m}$ and this implies that a significant amount of solar radiation can be converted into electricity. However, regardless of the intensity of the energy carried by a photon, it can only cause one electron to move from the valence band into the conduction band. This accounts for the relatively low efficiency of PV cells [5].

2.1. PVSyst Cell Temperature Model

PVSyst is a PV system modeling tool used in simulating and performing technical and economic analysis of PV power [7]. The operation of PVSyst is based on a cell temperature model derived from the Faïman cell temperature model and this is given in (Copper, Bruce, Spooner, Calais, Pryor and Watt, 2013) as:

$$T_c = T_a + \left(\frac{\alpha(G)(1-\eta_{STC})}{U_0 + U_1(V_{wind})} \right), \quad (2)$$

where T_c represents cell temperature, T_a is ambient air temperature, α is the adsorption coefficient of the module, G is the irradiance incident on the plane of the module or array in W/m^2 , η_{STC} is the efficiency of the PV module at STC condition, U_0 is the constant heat transfer component in $\text{W/m}^2\text{K}$, U_1 is the convective heat transfer component in $\text{W/m}^2\text{K}$, and V_{wind} represents wind speed in m/s. Both cell and ambient air temperature are in degrees Celsius.

The default values for PVSyst are 0.9 for α , 0.1 for η_{STC} , no dependence on wind speed, therefore $U_1 = 0$. Other default values are

- For free-standing arrays, $U_0 = 29 \text{ W/m}^2\text{K}$, $U_1 = 0 \text{ W/m}^2\text{K}$
- For fully insulated arrays (close roof mount), $U_0 = 15 \text{ W/m}^2\text{K}$, $U_1 = 0 \text{ W/m}^2\text{K}$

Sun Edison [7] proposed $U_0 = 26 \text{ W/m}^2\text{K}$ and $U_1 = 1.4 \text{ W/m}^2\text{K}$, which are the values that are used in this analysis.

2.2. Temperature Derating Factor for PV Cell Efficiency and PV Cell Output Power

According to Brihmat and Mekhtoub [8] the temperature derating factor for the PV cell efficiency and PV cell output power is defined as:

$$f_{temp} = 1 - |\beta_{STC}|(T_c - T_{STC}), \quad (3)$$

where f_{temp} represents the dimensionless temperature derating factor and β_{STC} is the power temperature coefficient of module in $\%/^{\circ}\text{C}$. The temperature coefficient of power indicates how strongly the PV array power output depends on the cell temperature, that is, the surface temperature of the PV array. It is a negative value once power output decreases with the increase of cell temperature. T_c represents the average daily cell temperature, in $^{\circ}\text{C}$ while T_{STC} is the cell temperature under standard test conditions (25°C).

When hourly meteorological data is used, the annual average cell temperature, T_{CA} is given as

$$T_{CA} = \left(\frac{1}{8760} \right) \left[\sum_{i=1}^{i=8760} \left(T_{a(i)} + \left(\frac{\alpha(G_{(i)})(1-\eta_{STC})}{U_0 + U_1(V_{wind(i)})} \right) \right) \right] \quad (4)$$

Therefore the temperature derating factor based on annual average cell temperature, T_{CA} is given as $f_{temp(A)}$, where

$$f_{temp(A)} = 1 - |\beta_{STC}|(T_c - T_{STC}), \quad (5)$$

2.3. The PV Efficiency and Output Power

PV cell efficiency at STC is given in [8] as

$$\left. \begin{aligned} \eta_{STC} &= \frac{W_p}{(A_{PV})(G_{STC})} = \frac{W_p}{(A_{PV})(1000 \text{ W/m}^2)}, \\ \text{where } A_{PV} &= \frac{W_p}{(\eta_{STC})(1000 \text{ W/m}^2)} \end{aligned} \right\} \quad (6)$$

and $W_p = \eta_{STC}(A_{PV})(G_{STC}) = \eta_{STC}(A_{PV})(1000 \text{ W/m}^2)$

η_{STC} is the maximum power point efficiency under standard test conditions, W_p is the rated power output of the PV module under standard test conditions in watts, A_{PV} is the surface area of the PV module in m^2 , G_{STC} is solar irradiance

at standard test conditions, that is 1 kW/m². In [8] it is shown that the PV efficiency varies linearly with temperature as follows:

$$\eta_{Tc} = \eta_{STC}(f_{temp}) \quad (7)$$

$$\eta_{Tc} = \eta_{STC}[1 - |\beta_{STC}|(T_{ca} - T_{STC})], \quad (8)$$

where all the coefficients are as earlier defined. Therefore, similar to equations (7) and (8), the annual average cell efficiency is given as η_{TCA} where;

$$\eta_{TCA} = \eta_{STC}(f_{temp(A)}) = \eta_{STC}[1 - |\beta_{STC}|(T_{ca} - T_{STC})] \quad (9)$$

Given a cell temperature, T_c and solar irradiance incident on the plane of the PV module, G , the PV power output is given by Omar, Hussin, Shaari and Sopian, [9]: as

$$\left. \begin{aligned} W_{Tc} &= W_P \left(\frac{G}{G_{STC}} \right) (f_{temp}) \\ W_{Tc} &= W_P \left(\frac{G}{G_{STC}} \right) [1 - |\beta_{STC}|(T_c - T_{STC})] \end{aligned} \right\} \quad (10)$$

Using hourly meteorological data, the expected annual energy output of the PV (E_{AE}) is given as the summation of the power deliver in the 8760 hours per annum. That is

$$E_{AE} = \sum_{i=1}^{i=8760} \left(W_P \left(\frac{G_i}{G_{STC}} \right) \right) \quad (11)$$

Equation (11) is given in watt-hours. The actual annual energy output of the PV when only the temperature derating

factor is considered is given as E_{AA} , where;

$$E_{AA} = [1 - |\beta_{STC}|(T_{ca} - T_{STC})] \left(\sum_{i=1}^{i=8760} \left(W_P \left(\frac{G_i}{G_{STC}} \right) \right) \right) \quad (12)$$

The Annual Average Percentage Thermal Loss (ATL%) is then given as

$$(ATL\%) = |\beta_{STC}|(T_{ca} - T_{STC}) \quad (13)$$

The Annual Thermal Loss (ATL) in Wh or kWh is given as

$$(ATL) = \left[\left| \frac{\beta_{STC}}{100} \right| (T_{ca} - T_{STC}) \right] \left(\sum_{i=1}^{i=8760} \left(W_P \left(\frac{G_i}{G_{STC}} \right) \right) \right) \quad (14)$$

3. The Simulation Process

The simulation is conducted with hourly meteorological data obtained from PVSyst software meteo-file for Dakar in Senegal, West Africa. The site coordinate for the data is 14.5° N, 17.0° W and altitude of 5m. The complete data consists of 8760 (one-year) hourly meteorological data. The parameters of the PV technologies used in the study are given in Table 1. PVSyst default value for the adsorption coefficient of the module (α) is 0.9. The cell temperature is computed using the following set of published [7] combinations of values, $U_0 = 26 \text{ W/m}^2\text{K}$ and $U_1 = 1.4 \text{ W/m}^2\text{K}$ [10, 11]. Table 1 shows other parameters considered in the simulation.

Table 1. Parameters of the PV Technologies Considered in the Simulation.

PV Technology	Monocrystalline Silicon (m-Si)	Polycrystalline Silicon (p-Si)	Amorphous Silicon (a-Si)	Microcrystalline (μ -Si)	Cadmium Telluride (CdTe) (CdTe)
Module efficiency η_{STC} (%)	18.4	14.1	6.0	9.5	10.7
Temperature coefficient of maximal powe β_{STC} (%/°C)	-0.38	-0.45	-0.19	-0.24	-0.25
STC Rated Output (Wp) in watts	100	100	100	100	100

4. Results and Discussion

An extract of one-day hourly meteorological data for Dakar is given in Table 2 while Figure 1 shows the cell temperature computed for each of the hours in that day.

From Table 2 and Figure 1, the cell temperature is equal to the ambient temperature in those occasions where the solar irradiance is zero. However, the cell temperature is greater

than the ambient temperature in those occasions where the solar irradiance is not equal to zero. The peak of the solar irradiance and cell temperature occurred at about 12 noon while the peak ambient temperature occurred between 2pm and 3pm. In all, the wind speed is constant at 5 m/s.

With average cell temperature of 34.3°C for the day, STC temperature of 25°C and $\beta_{STC} = -0.38\%/^{\circ}\text{C}$ for the monocrystalline silicon PV, the temperature derating factor for that day for that particular PV is

$$f_{temp(A)} = 1 - \left| \frac{\beta_{STC}}{100} \right| (T_{ca} - T_{STC}) = 1 - \left(\left| \frac{-0.38}{100} \right| (34.3 - 25) \right) = 1 - 0.03534 = 0.96466$$

Meanwhile, the Monocrystalline Silicon PV cell efficiency at STC is 18.4% so, the derated cell efficiency for that day is

$$\eta_{TCA} = \eta_{STC}(f_{temp(A)}) = 0.96466 \times 18.4\% = 17.45\%$$

From table 2, the total irradiation for the day is $24 \times 316.75 = 7602 \text{ W/m}^2$. The power output from the monocrystalline silicon PV for the day is

$$W_{Tc} = W_P \left(\frac{G}{G_{STC}} \right) (f_{temp}) = 100 \left(\frac{7602}{1000} \right) (0.96466) = 733.334532 \text{ Wh per day}$$

The thermal loss for the day for the monocrystalline silicon PV is

$$W_P \left(\frac{G}{G_{STC}} \right) \times \left(\left| \frac{-0.38}{100} \right| (34.3 - 25) \right) = 100 \left(\frac{7602}{1000} \right) \times 0.03534 = 26.865468 \text{ Wh}$$

The percentage thermal loss is therefore equal to

$$|\beta_{STC}|(T_{CA} - T_{STC}) = |-0.38|(34.3 - 25) = 3.534\%$$

Table 2. A One-day hourly meteorological data for Dakar and the corresponding cell temperature.

316.75	27.3	5	34.34913

Figure 1. One-day hourly meteorological data for Dakar and the corresponding cell temperature.

Table 3 shows the results of the effect of ambient meteorological parameters on the performance of the different PV technologies. In row 9 of Table 3, the average annual cell temperature of the PV technologies are the same (41.707°C) because the same adsorption coefficient of the module ($\alpha = 0.9$) is used for all the PV technologies. Out of the 8760 hours in a year, the solar irradiance is zero in more than half of the time, in those cases the PV output is zero. Also, in calculating the average annual cell temperature, out 4309 hours it is only in about 49.19% that the solar irradiance is above zero and hence contributed to the yearly energy yield of the PV module. Consequently, the annual average cell temperature is the total cell temperature when the solar irradiance is above zero divided by 4309. That gives the annual cell temperature of 41.707°C. When the total cell temperature is computed for all the 8760 hours and then divided by the 8760, the annual cell temperature is 32.65°C which includes those temperatures that

do not contribute to the PV energy yield.

Polycrystalline silicon has the lowest (worst) temperature derating factor (column 4 row 11 of Table 3) and hence it has the lowest (worst) energy output (column 4 row 12 of Table 3) as well as the highest (worst) thermal loss output (column 4 row 13 of Table 3). Column 4 row 4 of Table 3 shows that polycrystalline silicon has the highest (worst) temperature coefficient of -45%/°C which is the reason for the bad thermal behavior.

Row 15 of Table 3 shows normalised energy output which is the ratio of the PV annual energy output to the lowest PV annual energy output, which is 208157.709Wh per year. The normalised thermal loss is also obtained by dividing the PV thermal loss with the highest (worst) PV thermal loss which is 16921.891Wh per year. The normalised percentage thermal loss is also obtained by dividing the PV thermal loss with the lowest (worst) PV output which is 208157.709Wh per year.

17	Normalised % Thermal Loss	6.865	8.129	3.432	4.336	4.516

Figure 2. Normalised Energy Output Per Year and Normalised % Thermal Loss For The PV Technologies.

From the normalised figures in Table 3 and Figure 2, the amorphous silicon with the lowest temperature coefficient of $-19\%/^{\circ}\text{C}$ has the highest normalised annual energy output and the lowest normalised annual thermal loss. However, the amorphous silicon PV module used to achieve that is about three times the size of the monocrystalline silicon PV modules and about 2.5 times the size of the polycrystalline silicon PV module. So, the polycrystalline silicon PV module of the same size as the amorphous silicon PV module will give much higher energy yield. However, a comparative cost analysis is not conducted in this paper even though in practice a multidimensional comparative analysis is required in the selection of PV technology for any site.

5. Conclusion

The effect of ambient meteorological parameters on the performance of different PV technologies based on PVSyst thermal model has been presented. Even though the different PV technologies were exposed to the same ambient temperature, their cell temperature and output performance differs due to their unique thermal coefficients. Among the five PV technologies studied, amorphous silicon was found to have the best thermal response but the worst solar energy conversion efficiency. This makes the amorphous silicon to occupy much more space in order to achieve the same energy output as the other PV technologies studied.
