Abstract: In this paper, we consider the Bit Error Rate (BER) performance analysis of a cooperative relay communication system for Multi-Layer IDMA (ML-IDMA) using Maximal-Ratio-Combining (MRC) technique. We examine the effect of layers number on the performance and derive the average bit error probability of the Amplify-and-Forward (AF) relay scheme by using the closed-form relay link Signal-to-Noise Ratio (SNR). The proposed system has been simulated to evaluate the performance of ML-IDMA with different numbers of layers and different number of relays in the ML-IDMA cooperative environment. The simulation results show that the BER performance has been improved by about 4dB in the case of double layer ($K=2$) IDMA system with 4-relays, also, the saving in the band width is 50%. Finally, the BER performance has been degraded with increasing in the number of layers and the proposed system has improved the band width by about $1/K$.

Keywords: Cooperative Transmission, Multi Layers, MRC, AF

1. Introduction

Multiple-Inputs Multiple-Output (MIMO) technology is widely used due to its ability to offer high diversity and multiplexing gain. The Impracticality of mounting multiple antennas on a mobile device favor other techniques to be used in wireless communication and these techniques are also designed to have less impact on the size and power consumption of the devices. Recently, it has been shown that, in a cooperative system, two or more users cooperate with each other to transmit information to the destination. The cooperative users can share each other's antennas to form a virtual multiple antenna system so that a single antenna device can also benefit from the spatial diversity provided by the cooperative users. In such a way, cooperative communication allows a source node with a single antenna to share the antennas of other nodes, resulting in a form of virtual MIMO system.

User cooperation systems that utilize different cooperative signaling methods are known to improve cellular system capacity and coverage. The relay node physical limitation and allowed signaling complexity are the two criteria that limit the used cooperation system. In [1, 2] several cooperative diversity protocols were developed

and analyzed; Amplify-and-Forward (AF), Decode-and-Forward (DF), Detect-and-Forward (DtF), Estimate-and-Forward (EF) and Selective-DF (S-DF).

In AF protocol, relay nodes amplify the signals received from a source node and transmit the amplified version of the signals to a destination node. In EF, the relays forward an estimate of its received signals to the destination. For DtF, the relays detect the received signals and forward the detected symbols to the destination. For DF, the relay nodes decode the information received from the source and re-encode the signal before transmitting it to the destination. For S-DF, only those nodes that can correctly decode are selected to forward the signals to the destination [3].

As a kind of non-orthogonal multiple access scheme, Interleave Division Multiple Access (IDMA) has been widely researched [4], which is regarded as a special form of Code Division Multiple Access (CDMA) by treating interleaving index sequences as multiple access codes. IDMA performance is better than the conventional CDMA regarding the power and bandwidth efficiency. IDMA has common advantages with CDMA, diversity against fading and mitigation of the user interference problem, are two important ones. A low-cost turbo-type Multi-User Detection (MUD) algorithm applicable to the system with large numbers of users, which is crucial for high-rate

multiple access communication, is an important unique advantage of the IDMA that can add to its bandwidth efficiency as well as high transmission speed of data [5].

The principle of the IDMA systems is that the chip-level interleavers should be different for different users. In addition, a low-cost chip-by-chip iterative detection scheme can be utilized in the IDMA systems. Motivated by the concept of IDMA, Superposition Coded Modulation (SCM) partitions the data to multi layer, where each layer is treated by a user equivalently [6]. Multi-layer IDMA (ML-IDMA) is a special form of superposition coding scheme and it can be considered as a joint modulation/channel coding transmission scheme. Based on these backgrounds, according to the above observations, we propose a cooperative transmission scheme based on ML-IDMA.

In [5, 7-9], authors' have paid attention to the one layer IDMA cooperative system and without using any combiner technique at the destination. In this paper, we carry out the performance analysis of cooperative single user ML-IDMA scheme for equidistant relaying geometry with different number of layers and a Maximal-Ratio-Combining (MRC) technique; relay protocol that is used in this paper is Amplify-and-Forward (AF). The rest of the paper is organized as follows: in Section 2, we discuss the ML-IDMA system with AF Protocol; the experimental result is presented in Section 3; while conclusions and future works are presented in Section 4.

2. ML-IDMA System with AF Protocol

Amplify-and-forward is a simple cooperation scheme, in which relay does not require extra processing capability but still can achieve full diversity [10]. The only drawback in this scheme is that it amplifies the received signal along with inter-user channel noise. That means that it cannot eliminate the noise from the received signal, also termed as non-regenerative relaying protocol.

In an IDMA technique with an AF protocol, the source transmits a signal to a relay followed by amplification of the received signal that is controlled by an amplification factor as well as the power constraints. The amplification factor was shown to have an inverse relation to the received power [11].

We consider the cooperative system in Figs. 1-4. The system consists of a source (S), M relays, and a destination (D). The signal is transmitted from the source through two phases, first the source broadcasts the signal to the relays then the relays transmit the signals to the destination.

In our design, the source/user generates an input data sequence $d = [d(1), d(2), \dots, d(N)]$ which is converted by serial-to-parallel converter into K subsequences layers. Then the data, in each layer, is spread, interleaved and modulated, independently. Finally, all data in K layers are linearly superimposed to transmission then the source broadcasts the superimposed signal to the relays.

Figure 1. System model of cooperative ML-IDMA with multiple relays.

Figure 2. ML-IDMA transmitter (Source)

Figure 3. Relays with amplify-and-forward protocol

Figure 4. ML-IDMA Receiver (Destination)

For K -layer, the data sequence $d_k = [d_k(1), d_k(2), \dots, d_k(I)]$ is first spreaded, generating a spreaded sequence $s_k = [s_k(1), s_k(2), \dots, s_k(J)]$ then the spreaded sequence s_k is interleaved by a distinct chip-level interleaver π_k to produce a permuted sequence s_k . After interleaving, the randomly sequence s_k is modulated to $x_k = [x_k(1), x_k(2), \dots, x_k(J)]$ by BPSK. Where $I = N/K$, N is the user data length and I is the layer data length.

The transmitted signal x_s , after sum mission from K Layers, is then given by:

$$x_s(j) = \sum_{k=1}^K x_k(j) \quad j=0, 1, \dots, J \quad (1)$$

By assuming that each terminal has one antenna; each relay amplify the received signal and retransmit it to the destination and that the channels between the source and each relay is a quasi-static Rayleigh fading channel with Additive White Gaussian Noise (AWGN), the received signal $y_{s,r}$, at the relay, is given by:

$$y_{s,r} = \sqrt{P_t} h_{s,r} x_s + n_{s,r} \quad (2)$$

and the received power is given by:

$$E[y_{s,r}^2] = E[(\sqrt{P_t} h_{s,r} x_s + n_{s,r})^2] \quad (3a)$$

$$= E[(\sqrt{P_t} h_{s,r} x_s)^2] + E[n_{s,r}^2] \quad (3b)$$

$$= P_t |h_{s,r}|^2 + N_0 \quad (3c)$$

where $N_0=2\sigma^2$ is the average noise power.

The amplification coefficient is given by:

$$\beta = \sqrt{\frac{P_t}{P_t |h_{s,r}|^2 + N_0}} \quad (4)$$

By normalizing the power to $P_t=1$, $y_{s,r}$ is given by:

$$y_{s,r} = h_{s,r} x_s + n_{s,r} \quad (5)$$

$$\beta = \sqrt{\frac{1}{|h_{s,r}|^2 + N_0}} \quad (6)$$

The fading amplitude and noise were considered by amplification coefficient. Some other amplification coefficients were proposed in [12]. Amplification coefficients similar to this paper were also suggested by [10, 11, 13, 14]. This kind of amplification factor considers the channel response of inter-user channel and effect of noise when added to the received signal.

The signal after amplification is given by:

$$x_r = \beta y_{s,r} \quad (7a)$$

$$x_r = \beta(x_s h_{s,r} + n_{s,r}) \quad (7b)$$

The relayed signal when received at destination is given by:

$$y_{r,d} = h_{r,d} x_r + n_{r,d} \quad (8a)$$

$$= h_{r,d} (\beta(x_s h_{s,r} + n_{s,r})) + n_{r,d} \quad (8b)$$

The received signal at the destination at the first phase is given by:

$$y_{s,d} = h_{s,d} x_s + n_{s,d} \quad (9)$$

The total received signal for Maximum-Ratio-Combining (MRC) receiver is given by:

$$r = h_{s,d}^* y_{s,d} + \sum_{m=1}^M (h_{s,r_m}^* h_{r_m,d}) y_{r_m,d} \quad (10)$$

Using a single-path / one relay system, Eq. (10) is:

$$r = (h_{s,r}^* h_{r,d}) y_{r,d} \quad (11a)$$

$$r = (h_{s,r}^* h_{r,d}) h_{r,d} x_r + (h_{s,r}^* h_{r,d}) n_{r,d} \quad (11b)$$

Where $h = (h_{s,r}^* h_{r,d}) h_{r,d}$ and $n = (h_{s,r}^* h_{r,d}) n_{r,d}$

$$r = h \sum_{k=1}^K x_k(j) + n(j) \quad (11c)$$

Where “n” represents the composite noise, $h_{s,d}$ is the channel coefficient between the source and the destination, $h_{s,r}$ is the channel coefficient between the source and the relay, $h_{r,d}$ is the channel coefficient between the relay and the destination and “n” is a sample of an AWGN process with zero mean and variance σ^2 per dimension.

We adopted an iterative sub-optimal receiver structure, as illustrated in Fig. 4 which is composed by an elementary signal estimator (ESE) and K de-spreaders (DESSs). They are applied to solve inter-layer interference and the spreading constraint separately. The receiver performs the iterative processes to update the extrinsic information between ESE and DESSs [15, 16].

For the detection of layer- k , we can rewrite Eq. (11c) as:

$$r(j) = h x_k(j) + \xi_k(j), \quad j=1, 2, \dots, J \quad (13)$$

where, $\xi_k(j)$, represents the interlayer interference with respect to layer- k .

The ESE function is used to calculate the extrinsic log-likelihood Ratios (LLR) for estimating the transmitted signal. From the definition of the extrinsic LLR, the output of ESE function can be obtained by:

$$e_{ESE}(x_k(j)) = 2h \cdot \frac{r(j) - E(\xi_k(j))}{\text{Var}(\xi_k(j))} \quad (14)$$

where,

$$E(r(j)) = h \sum_k E(x_k(j)) \quad (15)$$

$$\text{Var}(r(j)) = |h|^2 \sum_k \text{Var}(x_k(j)) + \sigma^2 \quad (16)$$

$$E(\xi_k(j)) = E(r(j)) - h E(x_k(j)) \quad (17)$$

$$\text{Var}(\xi_k(j)) = \text{Var}(r(j)) - |h|^2 \text{Var}(x_k(j)) \quad (18)$$

The mean and variance of $x_k(j)$ can be calculated by the feedback from DESSs, as follow:

$$E(x_k(j)) = \tanh \left[\frac{e_{DESS}(x_k(j))}{2} \right] \quad (19)$$

$$\text{Var}(x_k(j)) = 1 - (E(x_k(j)))^2 \quad (20)$$

The mean and variance of the interlayer interference can be used to analyze and detect the signal of each layer. Then the updated extrinsic LLR from ESE function was proven to go through the layer-specific de-interleaver and gets into the DESSs iteratively [17].

3. Simulation Results

In this paper, we carry out the performance analysis of cooperative single user ML-IDMA scheme for equidistant relaying geometry with different number of layers and a MRC technique. The applied relay protocol is Amplify-and-Forward (AF), which is implemented for the system that uses Binary Phase Shift Keying (BPSK). MATLAB is used to simulate the obtained results. In this paper it is assumed that all stations are arranged at the edges of a square with a length of one. That means that all channels will have the same path loss and therefore the same average Signal-to-Noise Ratio (SNR).

To simulate the cooperative ML-IDMA scheme, we assume that the channel is Rayleigh fading channel, equidistant relaying geometry, BPSK signaling is used, frame length (N) = 512, Spreading Length (SP) = 32, number of relays (R) = 1..., 4, number of layers (K) = 2, 4 and number of iteration (it) = 3.

Fig 5. BER of cooperative ML-IDMA in Rayleigh channels with $K=2, 4$, $N=512$, $it=3$, $SP=32$ and $R=1$

Fig. 5 shows that there is degradation in the BER performance by increasing the number of layers. In the case of without relay, $K=2$ and $E_b/N_0=15$ dB, the BER performance was 1.9×10^{-4} while increasing K to 4, degraded BER performance to 6.6×10^{-3} . The observed degradation in the BER performance by increasing the number of layers is due to increasing in the signal amplitude which cause signal distortion. For single relay ($R=1$), in the case of double layer ($K=2$), the improvement of the BER performance is 1.67 dB compared to without relay system. Also in the case of four layer ($K=4$) and $E_b/N_0 = 20$ dB, the BER improvement was found to be about 2.6×10^{-3} when compared to without relay system as shown in Fig.5.

Fig.6 shows the improvement in BER performance by increasing the number of relays to $R=4$ at $K=2$ by about 4 dB when compared to without relay system. Fig. 7 show that $R=4$ is superior to the case of $R=1$ by about 3.5 dB at the BER of 10^{-4} . We can conclude that the co-operative environment, which added up two signals of different links, performs better than systems designed without relay environment. We can also see that when additional relay is

deployed, the performance in the co-operative environment gets better. The analysis showed that the addition of different path powers in co-operative environment results in a lower Bit-Error-Rate (BER).

Fig 6. BER of cooperative ML-IDMA in Rayleigh channels with $K=2, 4$, $N=512$, $it=3$, $SP=32$ and $R=4$

Fig 7. BER of cooperative ML-IDMA system in Rayleigh channels with $R=1, 2, 3, 4$, $K=2$, $N=512$, $it=3$ and $SP=32$

Fig 8. BER of cooperative ML-IDMA system in Rayleigh channels with $SP=8, 16, 32$, $R=1$, $K=2$, $N=512$ and $it=3$

Fig. 8 shows that increasing the Spreading Length (SP) can improve the performance significantly. By increasing the SP we were able to get larger spreading gain of the spread spectrum signal that improves the performance efficiency as the signal becomes larger.

4. Conclusion

In this paper, a cooperative communication scheme based on ML-IDMA technique is proposed for a network which has one source, one destination and multiple common relays. The proposed system is based on the chip-by-chip detection algorithm. Data reaches the destination through two different paths, i.e. a direct path from source to destination and a relayed path, where Amplify-and-Forward AF relay protocol is applied to the data that finally reaches the MRC combiner at the destination.

The proposed system has been simulated to evaluate the performance of ML-IDMA technique with different numbers of layers with Maximal-Ratio-Combining (MRC) technique in the cooperative environment. The simulation results showed that by increasing the number of layers, degradation in the performance was obtained but on the other hand the Band Width (BW) was saved by $(1/K)$.

The simulation also showed that the cooperative environment, which added up two signals of different links, performed better than the system designed without relays. When an additional relay was deployed, the performance in the cooperative environment got better. This improvement means that the addition of different path powers in cooperative environment actually results in a lower Bit Error Rate (BER) in the E_b/N_0 vs. BER curve. We also observed that, the performance of cooperative environment with two or more relays is better in all investigated layers. Future work will be done to investigate the performance of coded ML-IDMA cooperative schemes, OFDM ML-IDMA, Coded OFDM ML-IDMA.
